Hospitals as Insurers of Last Resort*  

Craig Garthwaite‡

August 2015  

Abstract  
American hospitals are required to provide emergency medical care to the uninsured. We use previously confidential hospital financial data to study the resulting uncompensated care, medical care for which no payment is received. Using both panel-data methods and case studies, we find that each additional uninsured person costs hospitals approximately $900 each year. Increases in the uninsured population also lowers hospital profit margins, suggesting that hospitals do not pass along uncompensated care costs to other parties such as hospital employees or privately insured patients. A hospital’s uncompensated care costs also increase when a neighboring hospital closes.  

* This research was made possible by a data-use agreement between the authors and the American Hospital Association that allows the confidential hospital financial data to be used for academic research. The agreement placed no constraints on the conclusions of the analysis except that they be factually accurate and the results do not represent the conclusions or opinions of the data provider. We thank Leemore Dafny, David Dranove, Joe Doyle, Amy Finkelstein, Emily Oster, Jesse Shapiro, and Heidi Williams for helpful discussions, and seminar participants at BU/Harvard/MIT Health Policy, the University of California-Irvine, Carnegie Mellon University, the University of Chicago, Cornell University, the University of Illinois, the Robert Wood Johnson Foundation at the University of Michigan, the New York Federal Reserve, Northwestern-IPR, The RAND Corporation, Rice University, Stanford University, Syracuse University, the University of Texas-Austin, Vanderbilt University and Yale University for useful comments. We thank Scott Bates for assistance with the American Hospital Association data, and we thank Mark He, Angela Li, Alen Makmudov, and Mariel Schwartz for excellent research assistance. Notowidigdo thanks the Initiative on Global Markets at the Booth School of Business for financial support. All authors are deeply grateful to the Robert Wood Johnson Foundation (Grant #72183) for financial support.

1. INTRODUCTION

Over the last decade, roughly 15 percent of Americans had no health insurance at any one time (US Census, 2013). Even after the full implementation of the Affordable Care Act (ACA), approximately 10 percent of the population will remain uninsured (CBO, 2013). Furthermore, many of those who gain coverage may be underinsured, facing large deductibles that exceed their available liquidity (Hamel et al., 2015). That lack of universal and complete coverage is partly the result of deliberate policy decisions. For example, the ACA excludes undocumented immigrants from many of its benefits and many state governments have, to date, not implemented the ACA’s Medicaid expansion. In addition, the benchmark insurance plans used to determine the magnitude of the ACA subsidies are only expected to cover seventy percent of average medical expenditures, leaving even the newly insured exposed to costly medical bills.

Those policy decisions are often justified based on the estimated cost to the government of covering the uninsured. It is misleading, however, to consider only the cost to the government – doing so fails to capture the full cost of the uninsured. At a minimum, these costs include the fact that the uninsured still demand health care and, due to a variety of factors, hospitals are mandated to treat them regardless of their ability to pay. For example, the Emergency Medical Treatment and Active Labor Act (EMTALA) requires that hospitals provide emergency medical treatment to all patients. In addition, non-profit hospitals must provide a community benefit in order to maintain their tax exemptions. And even beyond those legal constraints, medical ethics require that physicians treat certain patients regardless of ability to pay (Annas, 1985).

In this paper, we argue that, as a result of these factors, hospitals serve as the “insurers of last resort” in the American health care sector. When policymakers decide not to provide health insurance for a portion of the population that otherwise could not afford insurance, hospitals ultimately bear the cost of that decision. In

---

1 For example, Virginia Governor Bob McDonnell commented, “Virginia simply cannot afford to become the bank for a federally designed expansion of Medicaid.” Similarly, Georgia Governor Nathan Deal stated, “I did not judge it prudent to expand the eligible population of an entitlement program… since our state is already spending approximately $2.5 billion in state taxpayer funds annually.” Regarding immigration, former Speaker of the House, Nancy Pelosi, argued: “[i]t is stated very clearly in the Affordable Care Act, [and] it is our position in the immigration bill: no access to subsidies in the Affordable Care Act. Secondly, no access to Medicaid; no cost to the taxpayer. That has always been the Democratic position” [emphasis added].

2 Policymakers have long recognized the unique nature of the health care sector in that hospitals often provide services without compensation. As a result, policymakers have created funding streams to compensate hospitals for uncompensated care costs. Perhaps the most important of these funding streams are Disproportionate Share (DSH) payments. DSH payments are intended to compensate hospitals for providing care to low-income populations, and states are given broad latitude in how to spend the funds. In practice, though, DSH payments are much lower than the cost of uncompensated care provided by hospitals. Hospitals also receive other forms of government assistance, but most of these are not directly tied to the amount of uncompensated care that the hospitals provide and instead provide general support for the variety of other services hospitals provide to the community. As a result, they do not directly compensate hospitals when the hospital faces more uninsured patients. For example, when states reduce the generosity of Medicaid benefits there is no corresponding increase in the value of these local tax benefits.
2012, hospital uncompensated care exceeded $46 billion. By comparison, this amounts to nearly 30 percent of 2012 Medicaid payments for inpatient and outpatient hospital spending. Uncompensated care costs are also large relative to the industry’s profits. Holding all else constant, if hospitals only served paying customers, their 2012 profits would have been approximately 70 percent larger (Herman, 2014). To describe this role of hospitals, we study the determinants of hospital uncompensated care costs. We then examine whether this burden is equally shared across hospitals of different ownership types. Finally, we estimate whether hospitals bear the full financial burden through decreased profits.

First, we examine how shifts in the local demand for uncompensated care—arising from changes in the uninsured population—affect hospital uncompensated care. We use 28 years of previously confidential, hospital-level financial data. Those data were compiled by the American Hospital Association and made available to us through a data-use agreement. We estimate that each newly uninsured person leads to nearly $900 in uncompensated care costs. That association is remarkably robust to state and year fixed effects, the inclusion of time-varying state economic controls, and region-by-year fixed effects.

One concern with those state-level panel estimates is that they may be subject to omitted-variables bias or reverse causality. To address that concern, we complement our results with two case studies of large-scale public health insurance disenrollments. The two disenrollments both occurred in 2005, in Missouri and Tennessee. Estimates from these reforms isolate the effect of sudden, plausibly exogenous increases in the uninsured population. Exploiting both within- and across-state sources of variation, we find that these disenrollments increased hospital uncompensated care costs. The magnitude of the change in costs following those disenrollments is similar to our state-year estimates.

We then study the local supply of uncompensated care. In particular, we test whether uncompensated care is tied to each specific hospital, or whether the costs can spillover across hospitals following changes in market structure. As an example of such a spillover, consider the case of Saint Elizabeth’s Hospital in Belleville, Illinois. Hospital executives planned to move the main location out of the downtown area. This led executives at the remaining downtown hospital to fear that their hospital would “be overwhelmed and will get most of the area’s uninsured and Medicaid patients” (Galewitz, 2015).

To study such dynamics, we measure the effects of a hospital closure on neighboring hospitals. Defining the local market as either the county or the hospital service area (HSA), we estimate a statistically significant

---

3 This calculation assumes that the percentage of spending on inpatient and outpatient services is similar across the Medicaid Fee for Service and Managed Care programs.
decline in total uncompensated care provided in the market after a closure. However, this decline likely results from an overly strict geographic market definition. Supporting this argument, when we define the local market more broadly, using local commuting zones (Tolbert and Sizer, 1996; Autor and Dorn, 2013), we estimate a statistically significant increase in uncompensated care costs for the remaining hospitals in the market but no statistically significant change in the total uncompensated care provided. This nearly complete spillover of uncompensated care to the remaining hospitals suggests that the demand for uncompensated care is relatively inelastic and represents a market-level and relatively non-discretionary fixed cost for hospitals. The results also suggest that commuting zones may be a useful market definition when studying the health care consumption of non-elderly uninsured adults.4

Taken together, our results demonstrate the importance of hospital-provided uncompensated care in filling in the gaps of the social health insurance system in the United States. Importantly, the role of hospitals as informal insurers is not simply the unintended result of social insurance or the fact that the service provided is necessary for the survival of its customers. Both of these are characteristics of grocery stores, for example, which sell a vital product that is partially financed by social insurance in the form of food stamps. And yet, grocery stores that accept food stamps are not required to provide “uncompensated food” for individuals who are either ineligible for food stamps or have exhausted their monthly benefits. Similarly, this informal insurance does not mechanically occur because the government has chosen to use third parties in the provision of social insurance programs. Recently, the government has expanded the use of third parties as part of the Earned Income Tax Credit and the food stamps program without raising the costs of private firms (Kopczuk and Popleeleches, 2007; Saslow, 2013).

Instead, hospitals have become informal insurers as a result of deliberate policy decisions that (1) leave a portion of the low-income population without health insurance and (2) require hospitals to treat patients regardless of their ability to pay. As a result, Medicaid provides financial protection not only to its direct beneficiaries, but also to the hospitals that would have still been required to treat Medicaid recipients were they to be uninsured. That finding is consistent with the work of Finkelstein, Hendren, and Luttmer (2015), who estimate that Medicaid enrollees only value their insurance coverage at a fraction of the cost. Our results show that one

4 These results also contribute to a broader understanding of the industrial organization of health care markets. Gaynor, Ho and Town (2014) summarize the research on the structure of these markets. They focus on the welfare effects of changes in firm concentration. However, they do not discuss the role of uncompensated care. Our results demonstrate that changes in the structure of the local market can have meaningful, negative effects on firms’ patient margins. This can have several implications for research in this area. For example, a complete analysis of the benefits of increased concentration must account for the accompanying increased uncompensated care costs per hospital.
reason for this undervaluation is that uninsured individuals often receive care at hospitals without providing direct payment. As a result, both our results and those of Finkelstein, Hendren and Luttmer are consistent with a large fraction of Medicaid spending representing a transfer from the government to hospitals.

The existence of those transfers, however, does not speak to economic incidence. Many policymakers assume that hospitals simply pass on uncompensated care costs to privately insured patients by raising prices. For example, the text of the ACA states, “[t]o pay for [uncompensated care], health care providers pass on the cost to private insurers, which pass on the cost to families. This cost-shifting increases family premiums by on average over $1,000 a year. By significantly reducing the number of the uninsured, the requirement, together with the other provisions of this Act, will lower health insurance premiums.” Cost shifting was also cited by Chief Justice Roberts in the Supreme Court decision upholding the ACA’s constitutionality. Roberts wrote: “hospitals pass on the cost [of uncompensated care] to insurers through higher rates, and insurers, in turn, pass on the cost to policy holders in the form of higher premiums” (National Federation of Independent Business v. Sebelius).

Despite the frequent pronouncements of policymakers, the ability of hospitals to actually pass on uncompensated costs is not well established either theoretically or empirically (Dranove, 1988; Morrisey, 1994; Timmins, 2014; Dranove, Garthwaite, and Ody, 2014). We examine the potential for uncompensated-care cost shifting by studying how shocks to uncompensated care affect hospitals’ patient-care profit margins and other financial outcomes. If hospitals pass along all uncompensated care onto private insurers, then an increase in the uninsured population should not affect profits. We find, however, that increases in the uninsured population lead to a decline in patient-care profit margins. Those results demonstrate that, if cost-shifting occurs at all, hospitals cannot pass through all uncompensated care costs onto their privately insured patients in the form of higher prices.

We also examine whether hospitals pass these costs onto their employees or patients in the form or lower wages or lower patient-care quality. We find no evidence that the increase in uncompensated care costs results in lower payroll expenses, wages, or staffing levels. A back-of-the-envelope calculation suggests that hospitals absorb approximately two-thirds of uncompensated care costs, but the estimates cannot rule out that hospitals absorb all of the uncompensated care costs in the form of lost profits. We also estimate declines in hospitals’ net assets that are consistent in magnitude with these reduced profits, though these estimates are imprecise and not statistically significant.

---

5 In theory, pass-through will only occur at hospitals that had not set profit-maximizing prices. If non-profit firms do not solely maximize profits, then they may pass on uncompensated care costs to private insurers. But existing research indicates that many non-profit hospitals behave in a manner consistent with profit maximization (Dranove, Garthwaite, and Ody, 2014).
The results for hospital profits demonstrate that hospitals cannot fully shift uncompensated-care costs onto other parties such as hospital employees or insurers. The focus on profits also provides an additional benefit, an alternative to relying solely on the adjusted hospitals charges data used for our main estimates. As we describe below, uncompensated care charges may provide limited information on actual costs, and as a result estimates based solely on charges may provide a biased measure of true uncompensated care costs. We focus on hospital profits to alleviate such a concern. The profit estimates suggest that, in the case where hospitals are not able to pass any of their uncompensated care costs onto privately insured customers, each uninsured person costs hospitals $600. Therefore, the profit results provide an alternative estimate that does not require converting hospital charges to costs, and they also represent a lower bound if hospitals can pass through a share of their uncompensated care costs to other parties.

We next explore differences by type of hospital. We find that non-profit hospitals predominantly bear the burden of serving as insurers of last resort. For example, we find that increases in the uninsured population primarily affect the costs of non-profit hospitals. By contrast, for-profit hospitals are largely unaffected. Similarly, when a hospital closes, nearby non-profit hospitals bear a greater share of the burden of the spillover of uncompensated care costs.

Those findings shed light on whether nonprofit hospitals are simply “for-profits in disguise” (Weisbrod, 1988). That view, for instance, was held by former chair of the Senate Finance committee, Charles Grassley, who said “[n]onprofit hospitals and for-profit hospitals have often been indistinguishable” (Pear, 2015). In contrast to this prevailing belief, our findings show that non-profit hospitals fill the gaps in the existing social health insurance system to a degree that is not true of for-profit hospitals. This finding contributes to work that examines differences between non-profit and for-profit firms (Weisbrod 1988; Sloan and Vraciu 1983; Norton and Staiger, 1994; Cutler and Horwitz, 1998; Duggan, 2002; Horwitz, 2005; Horwitz and Nichols, 2009; Dranove, Garthwaite, and Ody 2014). Given the limitations of our data, we cannot conclude that this is the result of different intrinsic motivations of the firm, as opposed to differences in the selection of services that attract uninsured patients. However, we find that even when we limit the sample to similar geographies and hospital types, we continue to find evidence that non-profit firms bear a greater share of uncompensated care costs.

Finally, we conclude the paper by using our estimates to analyze the consequences of the ACA. We estimate that insuring 25 million more Americans under the ACA would reduce the uncompensated care costs of

---

6 While this lower bound is approximately two-thirds our estimate based on adjusted hospital charges, we note that if hospitals were able to pass along some of the cost to the privately insured (or adjust their costs in other ways) then this would suggest a higher cost per uninsured person.
hospitals by $20 billion, approximately 43 percent of the 2012 level. Additionally, hospitals in states that do not implement the ACA’s Medicaid expansion will face higher uncompensated care costs than those in states that implement the expansion. We calculate that the money states will “save” from not expanding Medicaid is less than the hospital uncompensated care costs generated by not expanding Medicaid. Our estimates thus suggest that the decision not to implement the ACA’s Medicaid expansion achieves savings for the government at the expense of hospitals.

2. **Why Do Hospitals Provide Uncompensated Care?**

Typically, firms only serve paying customers. But in health care, hospitals routinely provide care to patients who are unable or unwilling to pay. In 2010, US hospitals provided approximately $40 billion of care, 5.8 percent of total expenses, without payment. From 1984 through 2010, the absolute amount of uncompensated care steadily increased and the relative amount varied between 5.4 and 6.4 percent of expenses. To place this number in some context, consider that from 1992 through 2010, average hospital operating margins ranged from a low of 2.0 percent to a high of 5.5 percent.

Few previous studies have focused on hospital uncompensated care. A small literature has described trends in uncompensated care over time (Mann et al., 1997; Cunningham and Tu, 1997). To our knowledge, only two other studies have focused on the relationship between uncompensated care and the size of the uninsured population (LoSasso and Seamster, 2007; Davidoff et al., 2000). Both of these studies find a small association between public health insurance generosity and uncompensated care during the early 1990s. However, they focus on Medicaid expansions that were primarily aimed at children, which likely lowers their power to detect a relationship between public health insurance and uncompensated care. Two other studies conduct time series analyses of changes to state Medicaid programs (Blewett et al., 2003; APS Healthcare, 2006). More recently, DeLeire et al. (2014) examined publicly released financial data from for-profit hospital chains since the implementation of the ACA and found large decreases in the share of admissions from uninsured patients. The paucity of other studies is likely driven by the lack of publicly available data on hospital finances.

Given that private hospitals are large and sophisticated firms, the inability to secure payment for services rendered cannot be rationalized as a simple operational inefficiency. The open question is: why do hospitals

---

7 Firms often provide services prior to actual payment, and some consumers do default on their debts. But in most industries beyond health care, the firms are not forced to continue to do business with customers who do not pay.
continue to provide billions of dollars in care without compensation? Some of these costs are the result of true bad debt that firms in all sectors face, services for which the hospital expected compensation but for which they were unable to collect payment. A large portion, however, stems from charity care, services that the hospital provided without expecting compensation.

There are a variety of reasons that hospitals provide uncompensated care. In this paper, we consider two of the most-discussed reasons: (1) federal regulations and (2) preferential tax treatment. There are many regulations that govern how hospitals treat patients who do not pay. Perhaps the most important of these regulations is the Emergency Medical Treatment and Labor Act (EMTALA), which requires that hospitals treat all individuals requiring emergency care regardless of their insurance status. Passed in 1985, EMTALA was a federal statute that expanded on a number of state laws requiring hospitals to treat all patients regardless of their ability or willingness to pay. However, even after full implementation of EMTALA, analyses have shown that the uninsured still receive less intensive care for emergency treatments in hospitals (Doyle, 2005).

Beyond EMTALA, the health care sector is also unique in the large share of non-profit, private-sector firms. Over seventy percent of private hospitals are non-profit organizations. In exchange for being exempt from federal, state, and local taxes, these firms are expected to provide a community benefit. While there are many factors that contribute to a community benefit, such as medical research and teaching, perhaps the most discussed and easily quantified is uncompensated care (Nicholson et al., 2000). As a result, these hospitals may provide medical services to patients without compensation even if they do not enter the hospital through the ED.

---

8 It should be noted that professionals in other sectors do provide in-kind charitable contributions. For example, lawyers provide pro bono legal services. However, unlike much of the uncompensated care provided by hospitals, these services are small in magnitude and voluntary. To illustrate this point, consider lawyers in Florida, a state where attorneys are required to document their pro bono efforts. According to the American Bar Association, from 2009–2013, only half of Florida lawyers provided pro bono services in a year and the average annual pro bono hours per attorney in that state was 22. This suggests that these charitable services are not nearly as a large a feature in that market.

9 The line between bad debt and charity care is often unclear. For instance, some hospitals may classify care as bad debt when they expected the patient not to pay but still sent them a bill. The determination of uncompensated care as either bad debt or charity care is imprecise and varies across hospitals and over time. As a result, we focus on aggregate uncompensated care, the sum of bad debt and charity care, throughout our analysis.

10 In this paper we focus primarily on the decision of private firms to provide uncompensated care. Medical services without payment are also directly provided by government hospitals. These public hospitals are part of the explicit social safety net system as they are supported directly by federal, state and local governments. Although our precision is somewhat limited when we limit our analysis to public hospitals, we also find statistically significant increases in uncompensated care for public hospitals, with magnitudes broadly similar to what we find for non-profit hospitals (when normalized by expenditures, since these hospitals are typically smaller than non-profit hospitals on average).

11 Prior to 1969, IRS regulations required that hospitals provide charity care in order to qualify for their federal tax exemption. However, new regulations in that year broadened the criteria to include other activities that benefited the community (GAO, 2005).
Whether non-profit hospitals behave differently from for-profit hospitals remains an open question in the literature. Several studies compare the amount of uncompensated care provided by hospitals of different ownership types. In general these studies find that ownership status is a factor in the provision of uncompensated care by hospitals (Sloan, Morrissey, and Valvona, 1988).

However, subsequent work highlighted that these simple comparisons ignore the fact that firm ownership status and location are not exogenous, particularly for new entrants. To this end, Norton and Staiger (1994) find that non-profit and for-profit hospitals located in the same area provide similar levels of uncompensated care. Supporting this point, Duggan (2002) finds that non-profit hospitals respond similarly to for-profit firms when they compete in the same market as for-profit hospitals. Similarly, Horwitz and Nichols (2009) find that non-profit hospitals are less likely to offer relatively unprofitable services in markets where they compete with more for-profit rivals. Dranove, Garthwaite and Ody (2014) find that, across most dimensions, non-profit hospitals react to financial shocks in the same way economic theory predicts a for-profit firm would react. The one exception being that non-profit firms suffering financial shocks are more likely to stop offering relatively unprofitable services. As a result, many economists believe that non-profit and for-profit hospitals are broadly similar, a belief epitomized by Weisbrod’s (1988) characterization of non-profit hospitals as “for-profits in disguise.”

This paper’s results generally contradict that view. We find a consistent pattern of evidence that non-profit hospitals are more exposed to changes in demand for uncompensated care. That pattern persists even when we limit the sample to for-profit and non-profit hospitals in the same market. That said, we cannot rule out that non-profit hospitals may choose to serve areas within these markets where they are more exposed to demand for uncompensated care resulting from changes in the market’s uninsured population. However, we note that over the long term these decisions themselves are not fixed and therefore represent a choice made by non-profits.

Policymakers have created several programs intended to provide partial compensation for hospitals that provide care to low-income populations. The largest of these payments come from the Disproportionate Share Hospital (DSH) payments which are components of both the Medicaid and Medicare programs. The purpose

---

12 Horwitz and Culter (1998) describe the effect of a non-profit converting to a for-profit as “subtle,” and note that many of the differences between the two organizations (such as more effectively extracting money from public insurers) are quickly implemented by non-profit hospitals.

13 First established in 1986, Medicare DSH payments are a function of the number of patients that a hospital has who qualify for both Medicare and the Supplemental Security Income (SSI) programs as well as those that qualify for Medicaid but not Medicare.
of the Medicare DSH program is to compensate hospitals for the burden of treating a low-income population, which is believed to have higher costs than the average payment received under Medicare. Broadly speaking, hospitals that exceed a predefined threshold receive an adjustment in their Medicare reimbursements.

Similarly, Medicaid DSH payments are targeted at hospitals treating low-income populations and are “intended to recognize the disadvantaged financial situation of those hospitals because low-income patients are more likely to be uninsured or Medicaid enrollees” (Mitchell, 2013). The total amount of federal spending on DSH is fixed each year and does not increase with the size of the uninsured population. In 2012, $17.1 billion was spent on Medicaid DSH payments. Hospitals are eligible to receive DSH payments if their Medicaid inpatient utilization rate exceeds 1 percent. In addition, hospitals are guaranteed to receive some DSH payments if either their Medicaid inpatient utilization rate is at least one standard deviation higher than the mean for their state or their percentage of low-income patients exceeds 25 percent.

Outside of these restrictions, states are given broad latitude in the distribution of DSH payments. For example, Mitchell (2013) notes that in 2007 Oregon only distributed DSH funds to 9 of its 58 hospitals; that same year, every hospital in New Jersey received funds. As a result of the autonomy provided to states, it is not clear whether DSH payments effectively target hospitals providing large amounts of uncompensated care or instead assists hospitals that have large Medicaid populations.14 If hospitals are made financially whole by the DSH program for uncompensated care costs, then their role as informal insurers is limited. However, if DSH payments are primarily targeted towards hospitals with large numbers of publicly insured patients, then the decision of hospitals to provide uncompensated care represents a true financial cost of their role in the social safety net.

3. DATA

Our primary data on hospital uncompensated care costs consist of proprietary financial data obtained through a research partnership with the American Hospital Association (AHA). The data are collected as part of the annual AHA survey, which is the most complete measure of the structure and finances of American hospitals.15 We obtained AHA survey data from 1984 through 2011. The survey asks hospitals the amount of medical care

---

14 The uncompensated care costs we discuss in this paper do not include these underpayments and instead focus only on services for which the hospitals receive no compensation.

15 One concern is that – because the survey is handled by a trade association – hospitals may provide inaccurate information. Appendix Figure A1 compares uncompensated care data from the AHA to reports for the Tennessee Joint Annual Report, a mandated reporting system in that state. These data are remarkably consistent, showing that reports to the AHA, at least in Tennessee, are quite similar to those to the state regulatory body.
that they provide without any compensation. As described above, hospitals provide uncompensated care through two primary channels: charity care and bad debt.\textsuperscript{16} Charity care are services for which a hospital never intended to collect payment, whereas bad debts are costs related to services for which a hospital attempted to collect payment but was not paid (American Hospital Association, 2010). The methods of classifying uncompensated medical costs across these two categories vary greatly by provider and over time. For example, Rundall et al. (1988) state that for-profit hospitals are more likely to report uncompensated care as bad debt rather than charity care. By contrast, non-profit hospitals might be more inclined to define these costs as charity care. Over time, these patterns can change. For instance, a non-profit hospital may become concerned about an impression that they are not aggressive enough (or they are being too aggressive) in tracking down non-payments. Given this unclear distinction, we consider solely the sum of bad debt and charity care, total uncompensated care costs.\textsuperscript{17}

A second complication is that hospitals report the outcome as charges rather than costs. A well-known problem in the study of hospital finance is the growing spread between the list price that hospitals charge for a service and the actual payments these facilities receive from private payers. As a result, charge-based measures of uncompensated care provide an inaccurate description of actual costs. We therefore use a cost-to-charge ratio to approximate the actual costs of providing services.\textsuperscript{18} Since our data cover a long time period, we adjust the resulting uncompensated care costs to 2011 dollars using the CPI-U series, and we make similar adjustments for all other dollar values in the survey, such as patient revenue and hospital expenditures.

A final concern with the AHA data is that it focuses on dollars, not visits. For that reason, we also digitized the Joint Annual Reports (JAR) of health care facilities in Tennessee each year. These data are collected by the Tennessee Department of Health from licensed health care facilities in Tennessee. While many of the data in these reports are duplicative of the data in the AHA survey, the JAR data also include other outcomes, such as the number of admissions or visits by payer type.

\textsuperscript{16} Importantly, our definition of uncompensated care does not include any portion of hospital costs that exceed reimbursements from government programs such as Medicare and Medicaid.

\textsuperscript{17} Given these concerns, our data-use agreement with the AHA only allows us to study total uncompensated care in those data.

\textsuperscript{18} Specifically, we calculate each hospital's cost-to-charge ratio as total expenses divided by the sum of gross patient revenue and other operating revenue, and we average this measure across years for each hospital. Appendix Table A1 reports results using the following alternative cost-to-charge ratios: state-by-year average cost-to-charge ratios, annual average cost-to-charge ratios, hospital-by-year cost-to-charge ratios, and a “jackknife” measure which computes each hospital's average cost-to-charge ratio excluding the current year. One advantage of the jackknife measure is that if uncompensated care costs affect a hospital's profit margin (which would occur if hospitals cannot pass through the cost shock), then this will mechanically affect the hospital's cost-to-charge ratio. The results are qualitatively similar regardless of which cost-to-charge ratio we use, so we use the hospital average for simplicity.
We identify spillovers of uncompensated care across hospitals with systematic data on hospital closures. We obtained such data for 1987 through 2000 from reports generated by the Office of the Inspector General (OIG) at the Department of Health and Human Services. The OIG data were originally compiled by the Center for Medicare and Medicaid Services and various state agencies and associations (OIG, 2000). We merge the OIG records to the AHA hospital data and consider a hospital closed when it is both listed in the OIG data and no longer appears in the AHA hospital data. In total we identify 359 closures from 1987 through 2000.\footnote{An alternative way to identify hospital closures would be to identify hospitals that simply cease to exist in the AHA data. However, hospitals that merge but maintain separate physical locations are often combined into one entry in the AHA data. Since we cannot separate mergers from closures, this strategy would inaccurately classify facilities as closed when they remain open.}

Finally, for the state-panel analysis, we use the March Supplement to the Current Population Survey (CPS). The CPS is an annual survey of employment, income, and health insurance outcomes. The March CPS asks about insurance coverage in the previous year and we use these data to determine the share of the state population between the ages of 21 and 64 that lacks insurance each year.

4. THE DEMAND FOR UNCOMPENSATED CARE

This paper’s first goal is to study the demand for uncompensated care. In particular, we study how changes in the uninsured population affect hospital uncompensated care. Section 4.A. examines the relationship between the share of a state that is insured and the amount of uncompensated care provided by its hospitals. The section focuses on state-by-year variation in the size of the uninsured population. Section 4.B. complements those results with a case study, the 2005 Missouri Medicaid disenrollment. Section 4.C. focuses on a second case study, the 2005 Tennessee Medicaid disenrollment, which affected non-traditional Medicaid beneficiaries.

4.A. HEALTH INSURANCE PENETRATION AND UNCOMPENSATED CARE

The size of the uninsured population should be a major factor in the provision of uncompensated care. After all, if individuals are insured, then they need little uncompensated care.\footnote{The insured may also consume uncompensated care if they do not pay their cost-sharing expenses, and this may have become more common in recent years. For example, in 2006, only 3 percent of workers with employer-provided insurance had deductibles greater than $2,000 and only 10 percent had deductibles greater than $1,000. By 2012, these numbers grew to 14 and 34 percent respectively (Rae, Panchal, and Claxton, 2012).} To explore this relationship, Figure 1 presents the share uninsured versus total uncompensated care costs per capita. Panel A suggests a strong cross-state relationship between these two variables, while Panel B shows a similar relationship using changes within states over time. To further explore this relationship and quantify its magnitude, we estimate the cross-sectional relationship between state-level data on the share uninsured and uncompensated care costs. Table 1 presents...
estimates of a cross-sectional regression for 1990, 1995, and 2000. In all years, we observe a positive, statistically
significant relationship between the share of the population without insurance and hospital uncompensated
care costs. For example, in 1995, a ten-percentage-point change in the share uninsured was associated with a
$910 increase in uncompensated care costs per capita. This relationship is concentrated among hospitals with
an ED.

Of course, these cross-sectional relationships may simply reflect longstanding differences across states and
over time. For that reason, we estimate the following panel-data regression:

\[
y_{st} = \alpha_s + \delta_t + \beta \cdot \text{PercentUninsured}_{st} + X_{st}'\Gamma + \varepsilon_{st}. \tag{1}
\]

Here, \(\alpha_s\) are state fixed effects, \(\delta_t\) are year fixed effects, \(X_{st}\) is a vector of controls added to some specifica-
tions, and \(\varepsilon_{st}\) is an idiosyncratic error term that allows for arbitrary correlation between observations based on
the same state. The coefficient of interest, \(\beta\), represents the change in uncompensated care costs based on the
percentage of the population uninsured and is identified off of changes within states over time. We consider
two measures of uncompensated care costs: (1) uncompensated care costs per capita, and (2) uncompensated
care cost as a percentage of hospital expenditures.\(^{21}\) Note that when we consider uncompensated care costs per
capita, \(\beta\) can also be interpreted as the change in uncompensated care costs for each newly uninsured person.\(^{22}\)

Table 2 presents estimates of equation (1) for a variety of hospital samples. Panel A presents estimates for
the full sample of hospitals in the AHA. The estimates in column (1) suggest that each newly uninsured person
is associated with $856 in hospital uncompensated care costs. That estimate remains similar when we include a
set of time-varying state-level controls (column 2); region-by-year fixed effects (column 3); or both the region-
by-year fixed effects and state-level economic controls (column 4).

To place this estimate in context, consider that 8 percent of the uninsured report an inpatient visit each
year.\(^{23}\) Thus an uncompensated-care cost per uninsured person of $900 translates into a cost of nearly $11,000
per uninsured inpatient visit. By contrast, Pfuntner et al. (2013) estimate that each uninsured inpatient stay
costs $8,300. We note, however, that the AHA uncompensated care costs are based on both inpatient and out-
patient visits. Carper and Machlin (2013) estimate that inpatient services account for 71 percent of medical

\(^{21}\) All of the per-capita calculations use CPS estimates of the adult population between the ages of 21 and 64 in each state-year,
which matches same population used to calculate the percent uninsured.

\(^{22}\) That is, when per-capita uncompensated care is the outcome of interest, the state population is in the denominator in both
the outcome and the independent variable of interest. Thus, \(\beta\) represents both the effect of a change in a percentage-point in-
crease in the uninsured share and the effect of one additional uninsured state resident. This is one reason why we prefer the
specification in equation (1) to one that specifies the dependent variable in logs. We find similar pattern of results in a log speci-
fication.

\(^{23}\) Authors’ calculations based on the National Health Interview Survey.
spending relative to total inpatient, outpatient, and ED visits. This suggests a cost per uninsured person that utilizes medical services of approximately $11,690, which is very close to the scaled estimate above.

Columns (5) through (8) present a similar pattern for uncompensated care as a percentage of hospital expenditures. With the full set of controls, the point estimates suggest that a one percentage-point change in the share uninsured is associated with a 0.16 percentage-point change in uncompensated care as a percentage of costs. On average, uncompensated care accounts for 5.7 percent of expenditures, which means this is a 2.8 percent change in this outcome.

As described above, under EMTALA hospitals with an emergency department are required to treat emergent patients regardless of their ability to pay. Therefore, Panels B and C of Table 2 present regression estimates based on whether a hospital currently operates an ED. These estimates demonstrate that the increase in uncompensated care following an increase in share uninsured is entirely driven by hospitals with an ED. Facilities without an ED exhibit a small and statistically insignificant increase in uncompensated care when the share insured decreases. This is true regardless of the covariates included in the specification, the sample, or the definition of uncompensated care costs.24

Finally, we note that not all hospitals should be expected to experience increased uncompensated care. The AHA data contains information on a wide variety of hospitals, from large, general acute-care facilities to ambulatory surgical centers and rehabilitation facilities. Panel D presents regression estimates for a sample limited to adult and child acute-care facilities with an ED. These estimates are similar to the estimates for all hospitals with an ED, suggesting that nearly all of the change in uncompensated care costs following an increase in the share uninsured is borne by acute-care hospitals. This suggests that the observed relationship is not driven by a third, unobserved variable affecting the finances of the entire hospital sector.25

Overall, these estimates suggest a robust association between the demand for uncompensated care and actual uncompensated care costs. To further examine the magnitude of our estimates, we compare them to the results of the Oregon Health Insurance Experiment. Finkelstein et al. (2012) find that those who received new

24 There could be a concern that hospitals with an ED happen to be located in areas where there are more marginally insured individuals that demand uncompensated care when their insurance status changes. We address this concern by studying uncompensated care in hospitals that close their ED but otherwise remain open, and we compare uncompensated care in these hospitals before and after the ED closure. These results are reported in Appendix Table A2, and we find that uncompensated care drops by approximately 40 percent in the years following the closure of an ED.

25 Appendix Table A3 studies another potential difference across hospitals: whether they receive DSH funds. We divide hospitals into two groups based on whether they received DSH payments in 2005. (This is the first year we were able to obtain audited reports for the distribution of these funds at the hospital level.) The table suggests roughly similar effects of the uninsured on those two types of hospitals. This is consistent with DSH payments not fully compensating hospitals for the uncompensated care they provide.
insurance as a result of the Oregon Health Insurance Experiment consumed an additional $1,000 in hospital charges and saw a decrease in medical collections of $390. Assuming that only bad-debt charges are sent to collection agencies, and applying both Oregon’s 2009 cost-to-charge ratio and the distribution of charity care and bad debt in our AHA data, we estimate that each newly insured person reduced the uncompensated care costs for Oregon hospitals by approximately $550 in 2011 dollars with an upper bound of the confidence interval of nearly $1,021. This implied estimate is broadly similar to the main state-year estimate, above, of $887.

Although the state-panel estimates are robust to various control variables, we cannot rule out bias from unobserved, confounding trends. For example, a recession could increase the share uninsured in a state and also decrease the ability of previously uninsured individuals to pay for their hospitalization out of their own pockets. In addition, the results could be subject to bias due to reverse causality. Some researchers have hypothesized that it is the availability of charity care that induces consumers to become uninsured (Coate, 1995). Such a phenomenon would bias our results. To address this concern, we study large, sudden increases in the uninsured population. We focus on two such increases, which both arose from large-scale public health insurance disenrollments in Missouri and Tennessee. Overall, the results from these two case studies lead to similar conclusions as the state-level panel regressions above.

4.B. THE MISSOURI MEDICAID DISENROLLMENT

Following the 2001 recession, Missouri faced many years of revenue shortfalls. From 2001 through 2005, state revenues declined by 0.6 percent each year (Blouin et al., 2005). This resulted in budget cuts of over $2 billion over that time period, with nearly half of those reductions coming from social services, health, and mental-health services. Chief among these cuts was a sharp reduction in the generosity of the state’s Medicaid program in 2005. In 2004, Missouri Medicaid provided insurance for over 900,000 low-income state residents. As a result of the 2005 policy changes, approximately 150,000 residents lost access to Medicaid and SCHIP (Zuckerman, Miller, and Pape, 2009).

Prior to the cuts in Missouri the state’s Medicaid program was not notably generous and as a result those who lost coverage were similar to the traditional beneficiaries of public health insurance gaining and losing in-

---

26 Existing empirical evidence of this potential mechanism suggests that any effect is small (Rask and Rask, 2000; Herring, 2005; LoSasso and Meyer, 2006).
27 These are the two largest disenrollments during the sample period covered by our data.
28 The effect of the Missouri disenrollment exhibited little regional variation. Examining county-level Medicaid enrollment data, the county-level Medicaid caseload reduction ranged from 0.3 to 4.8 percentage of the population. The median reduction was approximately 2 percentage points and the interquartile range was 1.55 percent to 2.46 percent. As a result, in our empirical analysis, below, we are only able to compare changes in uncompensated care in Missouri to those in similar states – we cannot exploit within-Missouri variation in the effect of the disenrollment.
surance in the panel-data estimates above. For example, approximately half of those losing insurance were parents with incomes between 17 and 75 percent of the FPL (Ku and Solomon, 2005). As a result, the magnitude of the effect of the Missouri disenrollment serves as a useful benchmark for our panel-data estimates.

The reductions in the generosity of Missouri’s Medicaid program provide a sudden shock to the state’s uninsured population that should be unrelated to previous trends or other contemporaneous events in these markets. We begin by examining uncompensated care costs in Missouri versus neighboring states. Figure 2 presents uncompensated care costs in Missouri versus the other 6 states in the North-West Midwest over the same time period. Following the disenrollment, there was a sudden increase in aggregate uncompensated care for Missouri’s hospitals as compared to those in the comparison states. Importantly, prior to the disenrollment, hospital costs in Missouri and neighboring states followed roughly similar trends.

To identify the magnitude of the increase in uncompensated care, we turn to a difference-in-differences regression analysis:

\[ y_{st} = \alpha_s + \delta_t + \beta \cdot I\{s = \text{Missouri}\} \cdot I\{t \geq 2006\} + \epsilon_{st}. \]  

The variable \( y_{st} \) represents the uncompensated care per capita for state \( s \) and year \( t \). The model includes state fixed effects (\( \alpha_s \)), year fixed effects (\( \delta_t \)), and an error term (\( \epsilon_{st} \)).

The key coefficient of interest is \( \beta \), the difference-in-differences estimate of the effect of the change in Medicaid. This coefficient is identified by comparing outcomes in Missouri before and after the policy change to outcomes in neighboring states. The key identifying assumption is that outcomes in Missouri would not have evolved differently relative to other neighboring states in the absence of the disenrollment. The similar pre-trends in Figure 2 provide supporting evidence for that identifying assumption.

The first column of Table 3 presents the estimates of equation (2) and suggests an approximately $23 increase in annual uncompensated care costs per capita in Missouri compared to hospitals in surrounding states. While it is estimated that 150,000 lost public insurance coverage as a result of the Missouri disenrollment, Zuckerman et al. (2009) estimate that the number of uninsured in Missouri increased by only 103,000 from

29 The reduction in generosity came primarily from five policy changes. First, a reduction in the income limits for parents from 75 percent of the federal poverty line (FPL) to the income limits for the Temporary Assistance for Needy Families limits of approximately 17 to 22 percent of FPL. Second, the state increased premiums for children in families earning more than 150 percent of FPL (premiums were previously required for those earning more than 225 percent of FPL). Third, the state made families ineligible for SCHIP if they earned more than 150 percent of FPL and had access to employer provided insurance costing less than $335 per month. Fourth, the state eliminated the Medicaid Assistance for Workers with Disabilities (MAWD) program, which allowed disabled workers earning less than 250 percent of FPL to buy into the state Medicaid program. Finally, fifth, the state created an annual reinvestment program to ensure eligibility (Zuckerman, Miller, and Pape, 2009).

30 In particular, we include North Dakota, South Dakota, Nebraska, Kansas, Minnesota, Iowa, and Missouri in the sample.
2004–2006. Considering both ends of this range, our estimated change in per-capita uncompensated care costs suggests a cost per uninsured person of $556–$786. That range is slightly below the estimates from the state-year estimates above.

4.C. THE TENNCARE DISENROLLMENT

The Tennessee disenrollment involved the termination of a large Medicaid expansion program targeting a population not traditionally eligible for public health insurance. Specifically, the Tennessee expansion program targeted “uninsured” and “uninsurable” state residents regardless of income. As a result of the lack of an income requirement, the expansion enrollees had higher incomes than traditional Medicaid enrollees. In 1995, over 40 percent had incomes above 100 percent of the federal poverty line. In addition, relative to traditional TennCare enrollees, they were more likely to be white, between the ages of 21 and 64, and to not have children at home.

The expansion program made TennCare more expensive than anticipated, and, by 2001, the system faced a budget shortfall of over $300 million (Chang and Steinberg, 2009). As a result, beginning in late July of 2005, Tennessee disenrolled beneficiaries older than age 19 from the program. Approximately 4 percent of the non-elderly adult population of Tennessee lost public insurance coverage.31 Many disenrollees were able to secure private coverage, but in a previous paper we found that approximately 70,000 remained without insurance for many years after August 2005 (Garthwaite, Gross, and Notowidigdo, 2014). For them, the loss of insurance may have led to uncompensated care. It is that possibility that we assess here.

4.C.1 CROSS-STATE COMPARISON

Figure 3 presents uncompensated care costs for hospitals in Tennessee and those in other Southern states. Following the disenrollment, uncompensated care costs suddenly increased in Tennessee. Similar to Missouri, prior to the disenrollment, the costs for each set of states were similarly trending. However, in the years after the disenrollment there was a sharp change in uncompensated care costs for hospitals in Tennessee compared to hospitals in other Southern states.

Column 2 of Table 3 presents difference-in-differences estimates with uncompensated care costs per capita in each state as the outcome of interest. It suggests that, following the TennCare disenrollment, Tennessee hospitals provided approximately $42 more in annual uncompensated care costs per capita after the disenrollment compared to similar hospitals in other Southern states.32 Given the size of the TennCare disenrollment,

31 For more institutional details on the TennCare disenrollment, see Garthwaite, Gross, and Notowidigdo (2014).
32 In 2004, Tennessee hospitals provided approximately $670 million in uncompensated care.
this coefficient suggests that each newly uninsured person generated approximately $1,048–$1,678 in uncompensated care costs, with the range depending on the amount of crowdout exhibited by the expansion population.

These estimates are larger than the corresponding Missouri-based and state-year panel estimates, but that comparison is unsurprising. Roughly a third of the Tennessee expansion population were excluded from the private insurance market because of pre-existing conditions, and so were in poor health. A McKinsey and Company analysis found that the expansion population in its entirety had 40 higher Medicaid expenditures than a traditional TennCare enrollee (McKinsey, 2003). A forty percent increase over our main state-year panel estimate would be $1,242, which is very close to the midpoint of the TennCare estimates. Importantly, many of those expected to gain coverage through the Affordable Care Act come from a similar sub-population. Therefore the use of uncompensated care by this population is an important component of the potential change in costs from the ACA expansion.

4.C.2 WITHIN-TENNESSEE ANALYSIS

The cross-state evidence of an increase in uncompensated care in both Tennessee and Missouri suggests a causal relationship between the size of the uninsured population and hospital uncompensated care. A remaining concern is that another, contemporaneous event within each state is driving the estimates. For this reason, we next exploit the substantial, within-state variation in exposure to the TennCare disenrollment to estimate the effect of the disenrollment on uncompensated care.33

While the disenrollment was enacted simultaneously across Tennessee, the number of citizens who lost coverage varied a great deal across the state. We obtained county-level enrollment data from the Bureau of TennCare annual reports for 2004 and 2005.34 The percentage of a county’s population losing health insurance in the year after the disenrollment ranges from a low of 0.8 to a high of 9.1. The median county experienced a drop in enrollment of 3.3 percentage points, and the interquartile range was 2.7 to 5.0 percentage points. We aggregate these disenrollment data into the 14 health-department regions in the state identified by the Tennessee Department of Health. We construct regression models which interact the region-specific change in share

33 The lack of regional variation in exposure to the Missouri Medicaid disenrollment makes this type of analysis infeasible for that disenrollment.
34 These are the earliest available annual reports for TennCare. While quarterly reports for earlier years exist, those documents do not contain enrollment by county and eligibility category. Our attempts to receive earlier enrollment data from TennCare administrators were unsuccessful.
of population enrolled in TennCare with an indicator variable for the years following the disenrollment. Specifically, we estimate the following regression:

\[ y_{rt} = \lambda_r + \delta_t + \beta(\Delta\text{TennCare}_{r,2004-2005}) \cdot I\{t \geq 2006\} + \epsilon_{rt} \]  

(3)

where \( y_{rt} \) is the outcome of interest for region \( r \) and year \( t \). This model includes region-specific fixed effects (\( \lambda \)) and year fixed effects (\( \delta \)). Given the lack of reliable annual estimates of the population in each health department region, we consider a dependent variable that is the log of the uncompensated care in the region. We will then compare this magnitude to the estimate from a log-linear specification of equation (2).

The key coefficient of interest in equation (3) is \( \beta \), which estimates the effect of the TennCare disenrollment by exploiting differences across regions in the magnitude of decline in TennCare enrollments from December of 2004 to December of 2005 (\( \Delta\text{TennCare}_{r,2004-2005} \)), when the vast majority of the TennCare disenrollment occurred. The key identifying assumption is that the uncompensated care in these hospital regions would have evolved similarly in the absence of the disenrollment. While we cannot test this assumption directly, we show below that trends in uncompensated care in these regions were not evolving differently in the years before the disenrollment in a way that was correlated with our measure of exposure to the disenrollment.

We begin by comparing changes in unadjusted sample means across health department regions. Figure 4 depicts the relationship between \( \Delta\text{TennCare}_{r,2004-2005} \) and the change in total uncompensated care from 2004 and 2005 to 2006 and 2007. We observe a strong negative relationship: regions with larger decreases in TennCare enrollments experienced larger increases in uncompensated care costs. Figure 5 presents the results of a simple falsification test: it depicts the relationship between the same changes in TennCare enrollments in 2005 and differences in uncompensated care before and after 2002 rather than 2005. Importantly, the negative relationship that we observe in Figure 4 is not present in Figure 5.

We next quantify the magnitude of the changes in uncompensated care costs with a within-Tennessee regression analysis. Column (4) of Table 3 reports results from estimating equation (3) with the logarithm of the total amount of uncompensated care in each Tennessee health department region as the outcome of interest.\(^{35}\)

\(^{35}\) Our preferred within-state analysis exploits variation across Tennessee health department regions. We prefer this level of aggregation because it provides a large number of geographic areas (\( N = 14 \)). At the same time, health department regions are large enough to allow for a relatively accurate estimate of the change in TennCare eligibility in the area as well as to minimize the possibility of spillovers across areas, both of which would attenuate the results. In order to demonstrate that our results are not sensitive to this unit of analysis, Appendix Figures A2, A3, and A4 as well as Appendix Table A4 consider a number of alternate geographies. These include the 8 hospital referral regions (HRRs) and 81 hospital service areas (HSAs) in Tennessee, as well as the 9 Economic Development Districts established by the Tennessee Development District Act of 1965. The estimated impacts at the development district and the HRR level are similar in magnitude to the main estimates in Table 3, although the within-state estimates using HRRs are not precisely estimated (\( p = 0.327 \)). The estimated impact for the 81 HSAs is statistically
The first column demonstrates that hospital regions with a larger decrease in TennCare enrollment experienced a statistically significant increase in uncompensated care costs. Scaling this estimate by the average disenrollment in Tennessee suggests an approximately 18-percent increase in uncompensated costs. For the purposes of comparison, column (3) of Table 3 presents estimates of the cross-state specification using the logarithm of uncompensated care rather than uncompensated care costs per capita as the dependent variable. The estimates from the log-linear cross-state specification are remarkably similar to the scaled version of the within-state estimate.

A remaining concern with these within-state estimates involves pre-existing time trends specific to each region. We address this concern with a placebo exercise. Column (5) of Table 3 presents the estimates from a sample containing region-level uncompensated care costs from 1997–2004. We present the coefficient on an interaction between the (future) 2004–2005 change in TennCare enrollment with an indicator for the years after 2001. The panel, reassuringly, presents no evidence of a statistically or economically significant relationship.

### 4.C.3 Analysis of the Utilization of Hospital Services

A final concern with the results above, and all of the estimates that rely on AHA data, is that uncompensated costs may be driven by accounting rules, and thus may provide an incomplete picture of the actual care provided without payment. For that reason, we next explore the effect of the disenrollment on tangible medical services, such as inpatient admissions and outpatient visits. We obtain data on such outcomes for Tennessee hospitals from the digitized JAR data described in Section 3.

Figures 6(a) through 6(d) plot the change in inpatient admissions and outpatient visits in Tennessee hospitals by insurance status. Figure 6(a) suggests a sudden decline in such visits after 2005. That decline is consistent with the disenrollment; there were fewer TennCare beneficiaries after 2005. Figure 6(b) suggests that some of those who became uninsured, became self-pay patients at Tennessee hospitals. By contrast, Figure 6(c) suggests a slight increase in privately insured patients.36

significant at conventional levels but the magnitude is roughly half of the preferred estimates which use the larger health department regions in Table 3. This likely arises from a greater degree of measurement error, as discussed in more details below, HSAs are much smaller than the other areas. In addition, dividing Tennessee into HSAs may allow more spillovers in uncompensated care across smaller HSAs as compared to the other three geographic categories. Such spillovers indicate that the incidence of the TennCare disenrollment likely extends beyond the hospitals directly affected by the disenrollment and represents an important area of future work.

36 In our previous work (Garthwaite, Gross and Notowidigdo, 2014), we found that roughly half of those who lost TennCare coverage became uninsured, while the other half entered the labor market to procure private coverage. Figures 6(b) and 6(c) are consistent with that finding, in that we see an increase in both uninsured and private visits at Tennessee hospitals. The increase in private encounters in Figure 6(c) is small, but obscures a starker pattern for inpatient visits. Appendix Figure A5 presents the change in inpatient hospital visits for privately insured patients, and suggests a large, sudden increase after the disenrollment.
We compare the magnitude of this change in self-pay visits to the estimates based on the AHA data above. In 2007, there were approximately 980,000 self-pay visits. However, if the trend in self-pay visits had continued on its pre-disenrollment trend, we estimate there would have been only 740,000 self-pay visits. From 2002–2005 the average revenue from a TennCare patient was approximately $500 per visit. Accounting for the fact that Medicaid is known to pay below the cost of care, we estimate that the increase in self-pay visits cost hospitals approximately $138 million. Reassuringly, that number is broadly similar to the estimated changed in uncompensated care per capita for Tennessee in Table 3, which suggests that the disenrollment increased uncompensated care costs by $158 million.

5. The Supply of Uncompensated Care

The estimates above suggest that the demand for uncompensated care, which is a function of the size of the uninsured population, affects hospital uncompensated care costs. Hospitals in a local market serve as the “residual payer” for medical services following changes in the generosity of public health insurance. In this way, private hospitals provide an additional form of social insurance in that they are health insurers of last resort.

If the uninsured require a certain amount of medical care regardless of their ability to pay, and hospitals in a market serve as insurers of last resort, then the amount of uncompensated care hospitals provide should also be a function of the supply of medical services by other nearby hospitals. We examine this hypothesis next. To do so, we estimate the spillovers of both uncompensated and compensated care across hospitals following the closure of a local hospital. If the provision of uncompensated care occurs because the uninsured demand a minimum and unavoidable quantity of medical services for which they cannot pay, then closing competing facilities should not reduce the total provision of uncompensated care in a geographic area. Instead, each remaining hospital should see its uncompensated care costs increase, as uninsured patients are reallocated from the closing facility to the remaining hospitals in the market. However, if hospitals provide care solely at their discretion or if the very existence of a facility induces care that otherwise would not be demanded, then a hospital closure would reduce the total amount of uncompensated care in a local market.

The slight overall increase in privately insured hospital encounters is a combination of the large increase in inpatient admissions and a much smaller increase in ED visits. Such a pattern may result from the differential cost sharing for ED visits between Medicaid and most private insurance plans. There is debate in the literature about the effect of private insurance on the use of the ED (Kolstad and Kowalski, 2012; Miller, 2012; Anderson et al., 2012; Taubman et al. 2014). Appendix Figure A6 presents the number of ED visits by year in Tennessee. Prior to the disenrollment, the number of visits was smoothly increasing. However, beginning in 2005 there was a break from trend and the number of visits remains roughly level in the subsequent years. This decline provides suggestive evidence that insurance coverage increases rather than decrease the use of the ED.
5.A. UNCOMPENSATED CARE SPILLOVERS FROM HOSPITAL CLOSURES

We examine spillovers of uncompensated care across hospitals with a combination of the OIG and AHA data on hospital closures. In total, we identify 359 hospital closures from 1987 through 2000 that exist in our sample. The vast majority of the closures in our data are for acute-care hospitals. We therefore limit our sample to acute-care hospitals with an emergency department, the hospitals that are most likely to receive new patients following the closure of an acute-care hospital in their market.

A key question is how to define the local market. A market definition that is too narrow will miss out on patients who move to hospitals outside of the defined market. On the other hand, a market definition that is too broad will lack the power to detect economically meaningful spillovers. We begin our analysis at the county level, the market definition considered by Duggan (2002). Examining the patterns in our data, we find that when considering spillovers across hospitals, both counties and hospital service areas (HSAs) are too narrow of a market definition and we move to results using a definition based on the commuting patterns of local residents.

Using the OIG closure data, we identify a sample of 117 counties that suffered a large hospital closure as the first closure in this time period, where we define large closures as those where the closing hospital accounted for an above-average percentage of uncompensated care among closing hospitals, or more than nine percent of the total uncompensated care in the local market.\(^{37}\) In our sample of large closures, the mean closing hospital accounted for approximately 35 percent of the county’s uncompensated care costs in the year prior to its closure. Using this sample, we estimate the following event-study specification:

\[
y_{ct} = \lambda_c + \delta_t + \sum_{i=4}^{5} \beta_i \cdot I\{\text{years since closure}\} + \varepsilon_{ct}. \tag{4}
\]

Here \(\lambda_c\) are a set of county fixed effects, \(\delta_t\) are year fixed effects, and \(\varepsilon\) is an error term that allows for arbitrary correlation between observations from the same county. The coefficients of interest, \(\beta_i\), captures the change in uncompensated care costs in the county for the 4 years before and the 5 years after closure, with the year before the closure serving as the omitted category.

As outcomes, we focus on the number of hospitals in the county, the logarithm of uncompensated care costs for hospitals that do not close, and the logarithm of total uncompensated care costs in the county. Appendix Figure A13 presents the estimated change in the number of hospitals after a closure, which is relatively

\(^{37}\) Some markets suffered more than one closure throughout our sample period. For consistency across markets, we only include the first closure from these markets and only include markets where the first closure is a large closure. We find similar results to our main findings for a sample limited to only markets with a single large closure during the entire sample period.
stable in the years prior to the closure and then drops by approximately one in the year following the closure. Figure 7 suggests that the amount of uncompensated care provided by hospitals that do not close is stable prior to the closure and then increases by approximately 10 percent following the closure. The dashed horizontal line shows that the closing facility accounted for approximately 30 percent of uncompensated care costs in the county prior to it closing. The figure suggests that most of the costs previously born by the closing hospital are not transferred to the remaining hospitals in the county. Therefore, it should not be surprising that in Figure 8 the overall amount of uncompensated care provided by county hospitals falls by 20 percent following the closure. This demonstrates that either the closure of a hospital decreases the amount of uncompensated care consumed by the uninsured, or that uninsured patients travel outside of the original county of treatment to receive these services following a closure.

In order to distinguish between these two possibilities, we next consider other definitions of the local market. Two traditional market definitions in the literature are the hospital service area (HSA) and the hospital referral region (HRR). These areas provide measures of local health care markets and are defined by the historic utilization care for Medicare patients. HSAs are groups of zip codes in which more Medicare patients receive hospital care in the local hospital than in any single HSA (Wennberg et al., 1996). Therefore, HSAs are a fairly localized hospital market definition. By contrast, HRRs represent a collection of HSAs whose residents were referred for cardiovascular and neurosurgery treatments. This is a far larger market definition. In total, we have 2,886 HSAs and 162 HRRs in our analysis sample.

But these traditional definitions of hospital markets are likely not appropriate in our setting. HSAs likely suffer from the same problem as counties, in that after a facility closes, many uninsured patients leave the HSA to receive medical care. We would then erroneously conclude that a reduction in the total amount of uncompensated care following a hospital closure. On the other hand, HRRs are quite large. Therefore, the closure of a hospital may have little detectable effect on the provision of services in an area that large. In addition, both HSAs and HRRs are based on the flow of Medicare patients. Uninsured patients may seek care based on factors different from Medicare patients.

---

38 The number of hospitals in the local market does not fall by precisely one, because of entry of new AHA members, mergers of existing hospitals, and other (unobserved) closures.

39 Appendix Figure A7 presents estimates of equation (3) based on HSAs. The estimates for the HSA-based samples largely mirror those from the county-based analysis: a sudden increase in uncompensated care costs for the remaining hospitals, but an overall decrease in the amount of medical care provided without compensation. For the estimates using HRR as the unit of analysis, we are able to clearly identify the closure of a hospital based on the number of hospitals in the area. However, we cannot identify meaningful changes in the uncompensated care costs of remaining hospitals or in the amount of uncompensated care provided in the area. This is likely the result of the size of HRRs. For example, the average hospital closing accounted for
Therefore, we next consider the spillover of uncompensated care across hospitals located within the same commuting zone. Often used in the local labor markets literature, commuting zones are mutually exclusive collections of counties that have strong commuting ties between each other and weak ties to other areas (Tolbert and Sizer, 1996; Autor and Dorn 2013). These areas have the advantage of being larger than an HSA or county but smaller than an HRR. In addition, given that they are based on daily traffic patterns rather than the medical-care decisions of elderly insured patients, which may better capture the relevant catchment area for uncompensated care.

In our data, we identify 60 commuting zones that had a large closure as their first closure during our sample period. The first of these occurred in 1987 and the last in 1998. The mean hospital closure accounted for approximately 25 percent of the uncompensated care provided in the commuting zone in the year prior to the closure. Figure 9(a) displays the event-study estimates for the log of uncompensated care costs at hospitals in the commuting zone that did not close. These coefficients show little change in uncompensated care costs prior to the closure and then a large and immediate increase that accounts for the vast majority of uncompensated care costs from the closing hospital. Therefore, it should not be surprising that in Figure 9(b), there is at most a slight decline in the overall amount of uncompensated care provided in the commuting zone. None of the event-study coefficients are statistically distinguishable from zero.

There could be a concern that there is something about the act of closing a hospital that causes a general reorganization of the provision of uncompensated care the local market. If this were the case then our spillover estimates could be driven by this unobserved factor. To examine this question, Appendix Figure A8 contains estimates from a sample that contains all closures where the event study coefficient is allowed to vary based on whether there was a large or small closure. The large closure estimates broadly following the pattern in Figure 9(a). However, hospitals that remain open in markets that suffer a small closure see no noticeable change in their uncompensated care costs in the years after the closure. These estimates demonstrate that it is not some other feature associated with markets that suffer closures that are driving our main large closure estimates.

To more carefully estimate the magnitude of these spillovers we next estimated a differences-in-differences specification of equation (4) that replaces the individual post-closure coefficients with a single indicator variable for the 4 years after a closure. Panel A of Table 4 presents estimates of this specification for a dependent variable defined as the log of uncompensated care. Column (1) shows that, following a closure, there is an approximately six percent of the uncompensated care costs in the year prior to its closure, making this geographic aggregation underpowered to detect meaningful spillovers.
imately 17 percent increase in uncompensated care at the remaining hospitals in a commuting zone following a
closure. This accounts for most of the uncompensated care provided by the closing hospital, and as a result the
estimate in column (2) shows a statistically insignificant decline in total uncompensated care in the commuting
zone of approximately 6 percent. By contrast, a similar model estimated on the county-based sample shows a
statistically significant decline in uncompensated care of 25 percent.

5.B. REVENUE SPILLOVERS FROM HOSPITAL CLOSURES

In addition to the spillover of uncompensated care, one would also expect a spillover of profits from insured
patients. Appendix Figure A9(a) describes the change in revenue for hospitals that remain open in a county
after a closure. Following the closure, these hospitals experience an approximately 10 percent increase in reve-
nue. This increase represents only a fraction of the revenue earned by the hospital that closed. This can be seen
in Appendix Figure A9(b) which shows a sharp reduction in the consumption of medical services (as measured
by revenue) in the county following a closure. This reduction is at least partly the result of insured patients
seeking medical care at facilities located outside of their original treatment county.

Guided by our uncompensated care spillover estimates, we next consider revenue spillovers within a com-
muting zone. The average hospital that closes accounted for 20–30 percent of the revenue in its commuting
zone. Figure 10(a) shows a statistically significant increase in revenue for the hospitals in the commuting zone
that remained open following a closure. Figure 10(b) suggests that the total revenue for hospitals in the com-
muting zone decreased following a closure. To examine the magnitude of these changes, Panel B of Table 4
presents difference-in-difference estimates with hospital revenue as the dependent variable. Following a clo-
sure, we estimate a 6.4 percent increase in revenue for the remaining hospitals and an overall decline of 10 per-
cent of the revenue in the commuting zone at hospitals.

The revenue estimates suggest that even in commuting zones, hospital closures lead to a reduction in over-
all care provided by hospitals. This pattern may be driven by insured patients leaving the commuting zone to
receive medical care after a closure. We note, however, three facts. First, commuting zones are far larger than
counties, suggesting that the average insured patient would have to travel a great distance for care if they left
the region. Second, we do not find a statistically significant decrease in a commuting zone’s aggregate uncom-
penated care costs following a closure. Third, many hospitals that close have their facilities converted into
outpatient medical facilities. Given these facts, a reduction in the consumption of insured medical services fol-
lowing a closure would be consistent with a model in which the hospital care of insured patients is more discre-
tionary than the hospital care of uninsured patients. This could either be because closing a patients’ preferred
provider increases the cost of receiving these services and as a result these marginal services are no longer purchased. Or it could be that this care shifts to non-hospital medical settings such as an outpatient facility or a physician’s office. By contrast, we see no statistically significant reduction in uncompensated care. While the estimated change in these two outcomes of not statistically distinguishable, the patterns suggest individuals seeking uncompensated care at a hospital are less able to either defer care or switch the type of provider in response to a closure of their preferred facility.

6. WHICH HOSPITALS SERVE AS INSURERS OF LAST RESORT?

The estimates above show that hospitals serve as a vital part of the United States social insurance system in providing health care to the uninsured without compensation. A remaining question, however, is whether all hospitals equally bear this burden. In particular, it is unclear whether non-profit hospitals serve a singular role as private social insurers. A unique feature of the American health care sector is the large faction of firms that are structured as non-profit organizations. In our data, 51 percent of all hospitals and 73 percent of private hospitals are non-profits. These organizations are exempt from federal, state, and local taxes. In exchange for this preferential tax treatment, they are expected to provide a community benefit, an important component of which is charity care for the uninsured. There exists, however, a divisive debate over whether these organizations actually behave differently from for-profit hospitals.

We examine this question by testing whether non-profit hospitals respond differently to the share uninsured than for-profit hospitals. We begin by estimating our main state-year specification based on the ownership status of the hospital. Given the importance of EMTALA regulations, we would expect that all hospitals, regardless of their ownership structure, should experience an increase in uncompensated care costs resulting from uninsured emergency patients. However, if non-profit hospitals serve a unique role, we would expect them to exhibit a larger increase in uncompensated care costs following changes in the share uninsured.

Table 5 presents the effect of share uninsured on uncompensated care by hospital ownership. Columns (1) through (4) present estimates when the dependent variable is uncompensated care per capita. Panel A presents the estimates for non-profit hospitals and Panel B presents estimates for for-profit hospitals. Accounting for socioeconomic covariates and including region-by-year fixed effects, column (4) suggests that every newly uninsured person in a state is associated with $624 in uncompensated care costs for non-profit hospitals. The es-
timate for for-profit hospitals, however, has the perverse sign and is statistically insignificant at conventional levels. We can reject the null hypothesis that these two estimates are equal with a \( p \)-value lower than 0.001.

Estimates for the change in uncompensated care at for-profit hospitals may be imprecise because there are fewer for-profit hospitals, and they tend to be smaller than non-profit hospitals. This smaller size means that even if they change their provision of uncompensated care in response to changes in their local market, this may be hard to detect when measured as state-level uncompensated care per capita. For that reason, columns (5) through (8) present estimates when the dependent variable is uncompensated care costs as a percentage of overall expenditures. For non-profit hospitals, a 10 percentage point change in the share uninsured increases the percentage of overall costs from uncompensated care by 1.8 percentage points. By contrast, we find no statistically significant effect for for-profit hospitals. However, a test of the equality of the coefficients across these hospital types is not statistically significant at conventional levels.

One potential concern with the estimates for non-profit hospitals is that they represent a large and diverse set of hospitals. At the broadest level, these hospitals can be divided into those that are affiliated with a religious organization and those that are unaffiliated with a religious organization. These ownership structures could lead to differences in the intrinsic motivations of the firms. Appendix Table A5 presents estimates of the effect of the uninsured on non-profit hospitals based on their religious affiliation. The table presents very similar estimates for church-operated hospitals versus hospitals with no religious affiliation and suggests that the mission of different types of non-profit hospitals are not driving our results.

The smaller response among for-profit hospitals does not necessarily mean that these facilities simply deny services to the uninsured. For-profit hospitals may more carefully manage the \textit{intensity} of services provided to the uninsured residents in order to meet certain financial targets. Such a policy would allow them to comply with EMTALA without increasing overall costs. In addition, for-profit hospitals may simply locate in different areas or provide a set of services that are less amenable to the provision of uncompensated care. For example, for-profit hospitals may locate in markets in which fewer individuals are on the margin between being insured and uninsured. Changes in the statewide insurance coverage rate may not reflect changes for those markets. In accordance with this view, Norton and Staiger (1994) find that non-profit and for-profit hospitals located in the same area serve a similar number of uninsured patients, but for-profit hospitals choose to locate in areas with fewer uninsured people.

---

40 The remaining uncompensated care per capita is provided by government-owned public hospitals.
To explore that possibility, we next examine whether location can explain the difference here between non-profit and for-profit hospitals. Panels C and D of Table 5 present estimates of the same regression solely for hospitals located in HSAs that have both a non-profit and for-profit acute-care hospital with an ED. Given the small size of an HSA, these represent a fairly local market definition. The non-profit hospitals in these HSAs have a fairly similar response as the full non-profit sample. However, the for-profit hospitals in these HSAs have a much smaller response to changes in the share uninsured than the non-profit. The $p$-value on the test of equality of these coefficients is 0.15. The estimate for these for-profits is also approximately one-fifth the size of the estimate from the full for-profit hospital sample. This provides suggestive evidence that for-profit hospitals with a local non-profit competitor are even less exposed to increased uncompensated care costs resulting from changes in the share uninsured in the state.

These estimates suggest that, at least at the geographic level of the HSA, differential location cannot fully explain the differences in the response of for-profit and non-profit hospitals to changes in the demand for uncompensated care. It should further be noted that even if the remaining differences result from non-profit hospitals choosing to locate or remain in areas within HSAs that result in a greater burden from changes in the share uninsured, this is a difference in firm behavior.\(^{41}\)

All of these results suggest that non-profit hospitals bear more of the burden from changes in the demand for uncompensated care. We next ask whether the same is true after changes in the supply of uncompensated care. We test whether the closure of a nearby hospital affects non-profit hospitals differently from for-profit hospitals. Columns (3) and (4) of Table 4 present estimates of the change in uncompensated care costs following a closure by ownership of the hospital. Non-profit hospitals account for all of the increase in uncompensated care after the closure of a nearby hospitals. The effect among for-profit hospitals, by contrast, is negative and statistically insignificant. While these estimates are not statistically distinguishable from each other, this is primarily driven by the imprecision of the estimates for for-profit hospitals. Figures 9(c) and 9(d) present event-study point estimates for non-profit and for-profit hospitals respectively. Prior to the closure, the estimates for non-profit hospitals are statistically insignificant and near zero; they then rise in the post-closure

---

\(^{41}\) To further explore the robustness of these findings, we have also stratified the sample by ownership status in the two case studies. Similar to the state-year results, we find that non-profit hospitals bear the vast majority of the burden of these increased costs in Missouri following disenrollment. By contrast, the estimate for for-profit hospitals has the perverse sign and is statistically insignificant at conventional levels. In Tennessee, the estimates form a similar pattern as the estimates based on both the Missouri disenrollment and the main state-year sample. Non-profit hospitals account for the vast majority of the change in uncompensated care costs per capita following the disenrollment, and the change in uncompensated care costs among for-profit hospitals is positive but statistically insignificant at conventional levels.
years and become statistically significant. We do not see a similar post-closure increase in costs at for-profit hospitals.

Columns (3) and (4) of Panel B in Table 4 present the estimated change in revenue by ownership status. Following a closure, non-profit hospitals see a statistically insignificant increase in revenue of approximately 11 percent. The change in revenue for for-profit hospitals is roughly 5 percent and is also statistically insignificant at conventional levels. This pattern can also be seen in Figures 10(c) and 10(d) which contain event study coefficients for the change in revenue among facilities that did not close for non-profit and for-profit hospitals respectively. The lack of a similarly large revenue increase for for-profit hospitals suggests that some portion of the lack of the increase in uncompensated care may come from the for-profit hospitals serving different local markets from the non-profit hospitals within a commuting zone.

Overall, the results point towards for-profit hospitals being less affected than non-profit hospitals by factors that affect the supply and demand of uncompensated care. While each part of the analysis often lacks statistical power to precisely distinguish the responses of for-profit and non-profit hospitals, the pattern of results consistently suggests that for-profit hospitals are less affected.

7. CAN HOSPITALS PASS UNCOMPENSATED CARE COSTS ONTO PRIVATELY INSURED PATIENTS?

As a whole, the results above suggest a non-profit hospital’s own costs are a function of the supply and demand for uncompensated care in its local market. A final, remaining question is whether hospitals actually bear financial risk from these cost shocks or if they simply pass on these costs by raising the prices that they charge privately insured patients.

Researchers and policymakers have long debated whether hospitals are able to pass on financial shocks to their paying customers. Historically, this question has centered on the degree to which changes in the reimbursement rate for government insurance programs are passed along to the privately insured. For example, the AHA has historically referred to reimbursement cuts as a “hidden tax” on all Americans (Health Insurance Association of America, 1982). Ten years later, a similar argument was made to blunt the complaints of hospitals regarding Medicare reimbursement cuts (ProPAC, 1992). This argument found new life during the debate over the ACA, as proponents of the ACA argued that it would benefit every American by reducing uncompensated care and thus the associated cost shifting (National Federation of Independent Business v. Sebelius).

The attractiveness of cost-shifting arguments to policymakers is obvious. However, there is not strong theoretical or empirical support for this argument. Theoretically, it is unclear how hospitals could raise prices
on one group of patients following a lump-sum financial shock from another group. If hospitals were maximizing profits, then prices should have been optimal before the shock. For a price increase to be the optimal response to a financial shock requires two conditions. First, the hospital must possess some degree of pricing power in the private insurance market. Second, the hospital must not have fully exercised this power prior to the shock.

Dranove (1988) provides one such model of non-profit hospital behavior, where hospitals are maximizing both social welfare and profits. Under his model, in prosperous financial times hospitals keep prices low for the sake of social welfare. Following a lump sum financial shock, hospitals raise prices to preserve their profits.\(^{42}\) While Dranove (1988) finds evidence of such a phenomena in the 1980s marketplace, an increase in insurer market concentration likely leaves hospitals less able to set prices for privately insured patients (Gowrisankaran and Town, 1997). Accordingly, Dranove, Garthwaite, and Ody (2014) find that only a small subset of hospitals with considerable market power raised prices in response to financial shocks from the 2008 recession. Other hospitals adjust by altering other parts of their community benefit such as decreasing the offering of less profitable services such as trauma centers. The average hospital likely absorbed some or all of the financial shock through lower profit margins.

In an attempt to estimate the financial incidence of increases in uncompensated care costs, we next examine the changes in profits from patient services that come from changes in the local demand uncompensated care. If hospitals can fully recoup the lost funds in the form of higher prices on the privately insured, then their profit margins should be largely unaffected by increases in uncompensated care costs. In order to address this question we require a precise definition of hospitals profits. Given we are interested in the ability of hospitals to pass cost increases onto private patients, we focus our analysis on patient profits. We define patient profits as the direct revenue from treating patients minus the total costs. We focus on the profit margin, profits divided by revenues, as the independent variable.\(^{43}\)

We begin by returning to equation (1), with this definition of patient margins as the dependent variable. Table 6 presents estimates for different samples of hospitals. Panel A presents the estimates for all hospitals and suggests that a 10 percentage point increase in the share uninsured in a state is associated with a 1.1 percentage-point decline in the patient margin (standard error 0.8 percentage points). Panels B and C present the es-

\(^{42}\) Other work has found that in a model of capacity constrained physicians, providers can exhibit cost-following where a decrease in Medicare prices results in a decrease in private prices (Clemens and Gottlieb, 2014).

\(^{43}\) We rely on profit margins (as opposed to the logarithm of profits, for example) because of the large number of hospitals that have negative patient profits.
timates for non-profit and for-profit hospitals respectively. Note that our estimates of increases in uncompensated care costs in Table 5 show that non-profit hospitals bore the majority of these increases. Accordingly, these non-profit hospitals experience a 1.3 percentage point decrease in their patient margin following a 10 percentage point increase in the share uninsured. This estimate is statistically significant; the associated $p$-value is 0.01. The effect for for-profit hospitals is approximately one-sixth the magnitude of the estimate for non-profit hospitals and is statistically insignificant. It should be noted, however, that the estimates across ownership type are not statistically distinguishable, primarily because of the imprecision of the for-profit estimates.

These declines in patient margins show that non-profit hospitals are not able to pass all of the uncompensated care costs onto private insurers. We next conduct a back-of-the-envelope calculation to provide some understanding of how much of the cost may have been passed along. Based on our estimates above, in 2011 a 10 percentage point increase in the share uninsured in the United States would increase uncompensated care costs at non-profit hospitals by between $10.3 and $11.5 billion. This would decrease patient margins by between 2.0 and 2.2 percentage points. Our estimates suggest that hospitals absorb between 60 and 67 percent of the increased costs in lost profits on patient services.

While we are unable to rule out the non-profit hospitals absorb all of their uncompensated care costs as lost profits, a remaining question is whether some of the costs are passed along to either hospital employees or to patients in the form of lower quality. Table 7 presents estimates from a sample of non-profit hospitals with an ED, the set of hospitals that have a negative relationship between the share uninsured and patient margins. In order to have a balanced sample we also limit the data to hospitals for which we are able to obtain information on net assets.

Columns (1) and (2) of Table 7 present the estimated effect of the uninsured on uncompensated care costs per capita and patient margin. Those estimates for this sample are quite similar to those in Table 5 and Table 6. Columns (4) and (5) present estimates of the uninsured on total payroll per capita and the log of the average wage, respectively. These estimates provide little evidence that hospitals shift the burden of uncompensated care costs onto their employees. Columns (6) through (8) present estimates for the number of nurses, full time equivalent expenses, and labor costs. All of these employment-related assets are small and not statistically dis-

---

44 These costs represent forgone revenues, and therefore we must account for the fact that many of these newly uninsured patients likely came for social insurance programs that pay below the cost of providing care. Therefore, the low end of the range would occur if the change in the uninsured came from Medicaid patients, with an assumption that Medicaid is currently paying hospitals 90 percent of the costs of care (AHA, 2015). The high end of this range assumes that the patients come from payers that are reimbursing the hospital at zero profit level.

45 Data on the net assets of hospitals are obtained from the Medicare Cost Reports and include all of the hospitals fixed and non-fixed assets. These data were used by Dranove, Garthwaite, and Ody (2014) and supplied to us by those authors.
tistinguishable from zero. Together these estimates provide little evidence that hospitals pass on the cost of uncompensated care to patients through lower staffing levels.

The estimates in Table 7 suggest that hospitals are not able to shift the costs of uncompensated care onto their patients in the form of higher prices or lower quality care or onto their employees in the form of lower wages. This supports the hypothesis that hospitals absorb these costs through lower profits. However, hospitals must account for these lower profits in some part of their operation. If non-profit hospitals suffer large profit shocks, it may cause them to reduce contributions to their endowment or to draw down their endowments in order to cover operating expenses. To examine that possibility, column (3) of Table 7 presents the estimates for the relationship between the share uninsured in a state and net assets of non-profit hospitals divided by their revenue. The estimate is large and negative, however it is imprecisely estimated. Since they have the same denominator, the magnitude of this estimate can be directly compared to the estimated decline in the patient margin. While the change in the endowment is larger than the decline in profits, it is imprecisely estimated and is consistent with hospitals absorbing the uncompensated care costs through a slower growth in their net assets.

While hospitals are not able fully pass these costs onto the privately insured, this does not mean that they absorbed some of the costs and actually lost profits. It is possible that other revenue sources such as DSH payments or other government transfers could reimburse hospitals for these expenses. If this were the case, then we may see a decline in patient margin even if hospitals could pass this cost on to their privately insured patients. Again, we stress that this behavior should only apply to non-profit hospitals, who may consider the utility of privately insured patients in their objective function. Transfers from government sources should not affect the profit maximizing price for for-profit hospitals or non-profit hospitals that are choosing to simply maximize profits. Appendix Table A6 present estimates of the relationship between the share uninsured and both operating margins and total margins. Both of these estimates show a similar decline to the patient-profit margin, suggesting incomplete reimbursement for uncompensated care costs and an inability of hospitals to fully pass on uncompensated care costs onto the privately insured.

In addition, we note that these profit margin estimates provide a useful bounding exercise for concerns about measuring uncompensated care by adjusting hospital charges using a cost-to-charge ratio. These estimates of financial harm do not rely on any charge-based measures, and therefore our pass-through estimates could also represent a lower bound of the cost to hospitals in a situation of zero pass-through. Given our main estimates, this would suggest that even if hospitals are unable to actually pass any cost along than each uninsured person would cost approximately $600.
8. CONCLUSION

American hospitals serve as insurers of last resort, providing an informal form of social insurance that partially fills the holes in the existing social safety net. Hospitals are put in this role by a combination of factors that force them to provide health care regardless of the patient’s ability to pay. As a result, when governments do not provide health insurance, hospitals must provide it instead.

Our estimates can inform policymakers about the likely consequences of the ACA. That area is of substantial interest due to the recent decision, by some states, not to expand Medicaid. As of August 2015, 20 states have chosen not to implement the ACA’s Medicaid expansion, even though the federal government will fund 90 percent of the cost through 2020. As a result, approximately 5.2 million individuals in these non-expanding states will not receive coverage under the ACA (Holahan et. al, 2012). The state portion of the cost of covering these individuals as of 2022 is estimated to be $6.25 billion. Our estimates suggest that the uninsured population will generate approximately $6.4 billion in uncompensated care costs that year.

While hospitals may pass a small portion of these costs onto private insurers, they will be forced to either accept lower profits or adjust to higher costs in other manners. The Governor of Tennessee, Bill Haslam, alluded to that possibility when he made the following remarks about the potential ACA Medicaid expansion in that state.

We have to remember what the state went through seven years ago when it made the difficult decision to cut a lot of people from the TennCare rolls. We have to be very deliberate about making a decision to add that many and more back to the rolls, but I also understand that the decision isn’t just as easy as standing here today and saying, ‘We’re not going to expand Medicaid.’ There are hospitals across this state, many of them in rural communities, that are going to struggle if not close under the health care law without expansion, and that’s not something to take lightly (Haslam, 2013).

Future research is needed to explore the long-run effects of uncompensated care costs. Potentially, as Governor Haslam suggests, uncompensated care shocks may eventually lead some hospitals to close. Indeed, from 1990 to 2009, approximately 30 percent of the nation’s EDs closed, primarily due to hospital closures (Hsia, Kellerman, and Shen, 2011).

---

46 The cost of the expansion to states is phased in over time, and as of 2022 states are responsible for their full portion (i.e. 10%) of the expansion costs.
47 That number only includes uncompensated care costs at hospitals, not uncompensated care at other health-care providers. It is unclear how much uncompensated care physicians provide. Gruber and Rodriguez (2007) study payments made to private physicians’ offices and find that uncompensated costs are either negative or very small.
The overall welfare effects of such changes are unclear. On the one hand, ED closures and other reductions in services could reduce the efficiency of care provided, even to the insured. On the other hand, some existing research suggests that hospital closures have little effect on mortality (Joynt et al., 2005). Moreover, the results above suggest that, after a hospital closure, most of the uninsured are still able to find care by going to a different hospital in their commuting zone.

Lastly, this paper expands upon a large literature that has sought to estimate the benefits of public health insurance programs. The previous studies have focused on the effect of these programs on the beneficiaries themselves (Cutler and Gruber, 1996; Gross and Notowidigdo, 2011; Finkelstein et al., 2012). This paper broadens that focus to the benefits of public health insurance on the providers. Specifically, we note that health insurance provides financial protection not just to enrollees, but also to the private firms they visit.

We speculate that this financial protection informs the political economy of the Medicaid program. It is often argued that means-tested programs are not politically viable in the United States, that “a program for the poor is a poor program.” (McElvaine, 1984). Indeed, traditional cash welfare did not survive the 1990s and the generosity of other safety-net programs, such as food stamps, has recently been pared back (Shear, 2014). But Medicaid has never disappeared from a state and – absent a few isolated disenrollments – the program has only grown in size over time.48 Our paper suggests one explanation for this. A unique aspect of Medicaid is that it directly benefits not only the citizens it covers but also the hospitals they visit. Given that hospitals are an important political force at all levels of government, the factors requiring hospitals to provide uncompensated care may thus have unintentionally assured Medicaid’s long-term political stability.49

48 In 1987 approximately 8 percent of the population (20 million individuals) was covered by Medicaid. By 1997, this increased to roughly 11 percent (29 million individuals). By 2012 this had increased to over 16 percent (51 million individuals). In contrast, from 1990-2008 the number of cash-welfare beneficiaries fell from approximately 4 million to 2 million (HHS, 2004).

49 This can also be seen in the revealed preferences of hospitals in recent years. For example, as part of the state of Tennessee’s recent ACA Medicaid expansion, hospitals in that state jointly agreed to finance any expenses above the estimated cost of the program (Goodnough, 2014).

C. Five-Year Stacked Differences

Notes: The sample consists of the mean of the dependent variables calculated for each state and year from 1988 through 2011 for non-profit hospitals with an emergency room for which we observe their endowments. Panel B presents results when the sample consists of stacked three-year first differences among states, and Panel C presents five-year stacked differences. The standard errors in parentheses are robust to auto-correlation between observations from the same state; associated p-values in brackets. Year-times-region and state fixed effects not shown in Panel A, year-times-region fixed effects not shown in panels B and C. Average wages calculated as total payroll divided by number of employees. The outcomes in the first column and columns 5 through 7 are calculated as the sum across a state’s hospital, divided by that state’s population.
Figure 1. Share Uninsured and Uncompensated Care Costs

A. 2000 Cross Section

Uncompensated care per capita

B. 2000–2005 Changes

Change in uncompensated care per capita
Figure 2. Total Uncompensated Care Costs in Missouri

Uncompensated care costs (in millions)
Missouri only

Missouri

Other states in North-West Midwest

Note: This figure presents total uncompensated care costs in Missouri versus other states in the North-West Midwest, as reported in the AHA survey. See text for details.

Figure 3. Uncompensated Care Costs in Tennessee

Uncompensated care costs in millions, Tennessee

TennCare Disenrollment

Tennessee

Other states in South

Uncompensated care costs in millions, other Southern states

Note: This figure presents total uncompensated care costs in Tennessee versus other Southern states, as reported in the AHA survey. See text for details.
Figure 4. Changes in Uncompensated Care Costs within Tennessee, Before and After TennCare Disenrollment

Percent change in uncompensated care, 2004 and 2005 to 2006 and 2007

2004-2005 Change in TennCare enrollment divided by 2004 population

Note: This figure presents uncompensated care costs for the 14 health department regions in Tennessee, as recorded in the AHA survey. See text for details.

Figure 5. Changes in Uncompensated Care Costs within Tennessee, Before and After 2002

Percent change in uncompensated care, 2000 and 2001 to 2002 and 2003

2004-2005 Change in TennCare enrollment divided by 2004 population

Note: This figure presents uncompensated care costs for the 14 health department regions in Tennessee, as recorded in the AHA survey. See text for details.
Figure 6. Hospital Encounters in Tennessee, JAR Data

A. TennCare Encounters

B. Self-Pay Encounters

C. Private Encounters

D. Total Encounters

Note: This figure presents the number of hospital encounters (ED visits, outpatient visits, and inpatient visits) at hospitals in Tennessee, as recorded in the JAR data. The figures plot encounters in millions. In each panel, the dashed line plots predicted encounters based solely on 2002 through 2005.
Figure 7. Change in Uncompensated Care in County’s Remaining Hospitals After a Closure

Note: This figure plots point estimates from a regression of total uncompensated care for each county’s surviving hospitals on a series of exhaustive indicator variables for the years since the closure of a large hospital. The year before the closure is the omitted category. The data consist of GAO records of hospital closures combined with the AHA survey. See text for details. The dashed lines connect 95-percent confidence intervals.

Figure 8. Change in Total Uncompensated Care in County After a Hospital Closure

Note: This figure plots point estimates from a regression of total uncompensated care for each county on a series of exhaustive indicator variables for the years since the closure of a large hospital. The year before the closure is the omitted category. The data consist of GAO records of hospital closures combined with the AHA survey. See text for details. The dashed lines connect 95-percent confidence intervals.
Figure 9. Change in Uncompensated Care in a Commuting Zone After a Hospital Closure

A. Uncompensated Costs in Remaining Hospitals

B. Total Uncompensated Care in Commuting Zone

C. Uncompensated Costs in Remaining Non-Profit Hospitals

D. Uncompensated Costs in Remaining For-Profit Hospitals

Note: This figure plots point estimates from a regression of hospital uncompensated care in each commuting zone on a series of exhaustive indicator variables for the years since the closure of a large hospital. The year before the closure is the omitted category. The data consist of GAO records of hospital closures combined with the AHA survey. See text for details. The dashed lines connect 95-percent confidence intervals.
Figure 10. Change in Revenue in a Commuting Zone After a Hospital Closure

A. Revenue in Remaining Hospitals

B. Total Revenue in Commuting Zone

C. Revenue in Remaining Non-Profit Hospitals

D. Revenue in Remaining For-Profit Hospitals

Note: This figure plots point estimates from a regression of hospital revenue in each commuting zone on a series of exhaustive indicator variables for the years since the closure of a large hospital. The year before the closure is the omitted category. The data consist of GAO records of hospital closures combined with the AHA survey. See text for details. The dashed lines connect 95-percent confidence intervals.
