Wall Street and Silicon Valley: 
A Delicate Interaction*

Abstract

Entrepreneurs and venture capitalists are concerned about investors’ beliefs in asset markets because these beliefs shape the value of a potential IPO and the possibility to expand. Investors’ beliefs, on the other hand, can be influenced by startup activity because the latter may contain valuable information about eventual profitability. This two-way feedback is shown to generate excessive, non-fundamental, waves in startup activity, IPOs, and asset prices. Policies that “lean against the wind” can improve welfare, without requiring the government to have any informational advantage vis-a-vis the market.

Keywords: beauty contests, IPO waves, hot IPO effects, mis-pricing, heterogeneous beliefs, information-driven complementarities, volatility, inefficiency.

1 Introduction

The arrival of new, unfamiliar, technologies—e.g., e-commerce in the late 90s—is often associated with joint spikes in startup activity, initial public offerings (IPOs), and asset prices. Do these spikes reflect the efficient response of the economy to available information about the likely profitability of the new technologies? Or are they symptoms of excessive waves of optimism and pessimism?

We study how the answer to this question depends on a particular two-way feedback between entrepreneurial activity (“Silicon Valley”) and asset markets (“Wall Street”), which we expect to be particularly relevant in this context. On the one hand, Silicon Valley is concerned about investor sentiment in Wall Street because this determines the value of a possible IPO and the possibility to expand. On the other hand, Wall Street monitors startup activity, venture capital, and other indicators of real investment because these variables may aggregate dispersed information about the underlying fundamentals. The first channel is the subject not only of the macro-finance literature at large but also of the literature on “IPO waves,” with which we connect below. The second channel has received little attention in the specific context of interest, but seems to find support in a large empirical literature, tracing back to Chen, Roll, and Ross (1986) and Cutler, Poterba, and Summers (1989), that documents the response of asset prices to news about real economic activity at both the macroeconomic and the sectorial level.

Our paper shines the spotlight on the interaction of these two channels. We argue that this interaction can give rise to excessive, non-fundamental, waves of optimism and pessimism in startup activity, IPOs, and asset prices. The amplification of “noise” or “animal spirits” and the associated inefficiency are largest when there is more uncertainty, less consensus, and more scope for social learning—which suggests that the arrival of new, unfamiliar, technologies may be especially conducive to such phenomena.

Model Preview. Our “Silicon Valley” features a continuum of entrepreneurs, who move in two stages. In the first stage, they decide whether or not to start a project with a new technology, using internal funds and/or venture capital. We think of this stage as the startup stage. In the second stage, those entrepreneurs who started a project can expand its scale by raising funds in “Wall Street,” by selling equity shares to a continuum of external investors. We think of this stage as the IPO stage. All agents are imperfectly informed about the long-run profitability of the new technology (the underlying “fundamental”).

As anticipated above, at the core of the model is a two-way feedback between these two groups of agents. In the first stage, when an entrepreneur chooses whether or not to start a project, she bases this decision on her expectations about future IPO prices, which will determine her capacity to expand and her eventual payoff. In the second stage, investors base their demand for shares on, inter alia, the information they can extract from their observation of (a signal of) aggregate startup activity. Through this information channel, startup activity has a positive effect on investor demand and IPO prices.

---

1We do not study the incentive problem between entrepreneurs and venture capitalists and, in fact, we do not even explicitly incorporate venture capitalists. However, we like to interpret the entrepreneur in our model as a “team” between an entrepreneur and a venture capitalist, with the former providing the relevant know-how, the later providing the funds for a startup, and the two sharing information and payoffs. More generally, we think of the startup decision as a proxy for a broad range of real investment decisions taking place before firms go public.
Main results. In our model, aggregate startup activity is driven by two shocks: the true fundamental and the entrepreneurs’ “animal spirits.” In the most literal interpretation of the model, animal spirits represent correlated noise in the entrepreneurs’ information about the new technology; but it is straightforward to recast this noise as a correlated bias in beliefs (“irrational exuberance”), or a correlated taste shock. Our first result shows how the aforementioned two-way feedback amplifies the effects of animal spirits, or noise, on startup activity and IPO volume.

To understand this result, consider first the IPO stage. Investors are rational and understand that high startup activity could be the product of either strong fundamentals or correlated entrepreneurial exuberance. But they cannot tell the two forces apart. It follows that, at the IPO stage, investors’ demand and asset prices tend to increase with the entrepreneurs’ animal spirits—and, by implication, so does the amount of capital that can be raised in the IPO market.

Next, consider the startup stage. At this point, entrepreneurs face uncertainty about both the underlying fundamental and the likely IPO price. They understand that, in equilibrium, IPO prices tend to move in the same direction as the startup activity of other entrepreneurs conditional on the fundamental. This means that the startup stage reduces to a game of strategic complementarity: conditional on her belief about the fundamental, an entrepreneur is more willing to start a project (and subsequently enter the IPO market) when other entrepreneurs do the same. Similarly to the literature on beauty contests (Morris and Shin, 2002, Angeletos and Pavan, 2007), this complementarity amplifies the equilibrium effects of noise, or animal spirits, on startup activity and, thereby, on IPO volume, too.

A complementary interpretation is that, because of the informational channel, entrepreneurs end up engaging in a form of speculation: whenever entrepreneurial animal spirits are high, the typical entrepreneur anticipates the investors to overvalue her project, and this increases her incentive to start a project and subsequently do an IPO, as a means for taking advantage of such mis-pricing. Finally, because this kind of behavior ultimately reduces the precision of the information revealed to the investors, the non-fundamental movements in IPO prices and capital expansion are also amplified. In short, non-fundamental volatility is amplified across the board.

Our second result shows that these effects are excessive, not only relative to a counterfactual world where our mechanism is absent (e.g., because the investors are perfectly informed at the IPO stage), but also relative to the following constrained-efficiency benchmark: a planner who does not have superior information over the market, and cannot directly observe either the underlying shocks or the entrepreneurs’ information, but can influence the entrepreneurs’ incentives via subsidies/taxes contingent on publicly available information, such as IPO prices. This benchmark provides a rationale for policy interventions that improve over the laissez-faire equilibrium without requiring the policymaker to know the different drivers of the waves of optimism and pessimism in startup activity and IPO prices.

To understand this result, note that the planner wants the entrepreneurs to ignore the strategic complementarity, and not to base their decision on any expected IPO mis-pricing, because this represents only a zero-sum transfer from one group of agents to another. Furthermore, the planner wants the entrepreneurs to internalize how their startup choices affect the precision of the information upon which
capital will be raised at the IPO stage. Both of these forces amount to reducing the non-fundamental volatility in startup activity and subsequent investment relative to the laissez-faire outcomes.

What kind of policies could help implement, or at least proxy, the planner’s solution? The key is to “lean against the wind”, in the sense of penalizing startups/IPOs when prices are high and subsidizing them when prices are low (relative to the unconditional mean). This can be achieved by imposing either a price-contingent tax on the entrepreneurs or a “Pigou tax” on financial traders. In our model, the former policy is strictly preferable because it is the entrepreneurs’ choices and not the traders’ ones that need to be corrected, but the latter strategy goes in the right direction, too.

IPO waves. As already alluded to, the idea of non-fundamental waves of optimism and pessimism connects our model to the large literature on IPO waves (see Ritter and Welch, 2002, for an overview). Two key facts from this literature are particularly relevant for our analysis. First, IPO activity tends to be clustered in time: there are periods with very little action, and periods with large spikes. Figure 1, taken from Pastor and Veronesi (2005), illustrates this pattern. Second, there is a “hot IPO effect”: the presence of more IPO activity by firms in a particular sector tends to increase the price at which a given firm in that sector can do an IPO, holding constant both various proxies for sector-specific fundamentals and economy-wide IPO activity and asset prices. Our model is broadly consistent with these two facts and provides a particular interpretation of them: a hot IPO market can reflect either fundamentals or noise, but the role of noise is both amplified and excessive from a welfare viewpoint.

A third key fact documented in this literature is that IPO waves tend to predict eventual underperformance, relative to comparable pre-existing firms or seasoned offerings. Several authors interpret such underperformance as a symptom of irrationality. Pastor and Veronesi (2005) criticize this view on the

Figure 1: IPO waves over time, reproduced from Pastor and Veronesi (2005).

---

basis that it assumes that the periodic market mis-pricing can somehow be detected by the owners of the firms going public but not by the investors providing IPO funds and counter-proposes that the apparent anomaly can be rationalized by time-varying risk premia. We are not interested in resolving this debate; and we have little to say about this specific fact, because our model assumes that investors are both fully rational and risk neutral. But we offers two new angles on the whole issue.

First, we provide a justification for policies that lean against IPO waves even when all agents are fully rational. Second, we identify a new testable prediction: underperformance conditional on a wave being driven by correlated noise. If our theory is correct, real-world investors and external observers alike may not know what shock is causing the wave and may detect no mis-pricing in real time; however, an econometrician should be able to detect the aforementioned conditional form of underperformance using ex-post information, as we explain in more detail in Section 7.

**Beauty contests.** Another integral part of our contribution is to show how the two-way feedback under consideration gives rise to strategic complementarity in startup activity and IPOs. This connects us to a literature that has sought to operationalize Keynes (1936)'s famous beauty-contest metaphor for asset markets (Allen, Morris and Shin, 2006; Bacchetta and Wincoop, 2005; Cespa and Vives, 2012; Kassa, Walker and Whiteman, 2014). Relative to this literature, we shift the focus from asset prices to real investment. More importantly, we justify the implicit suggestion that “beauty contest are bad” from a welfare standpoint, by showing that the strategic complementarity induced by our mechanism introduces a wedge between private and social returns.

This property contrasts with the efficiency of another kind of beauty contest in real economic activity, that originating in pecuniary externalities in the textbook business-cycle framework (Angeletos and La'O, 2010, 2020). It also explains why our normative lessons extend to the variant model of Section 6, which lets startups compete for funds in the IPO stage. This “neoclassical” force naturally introduces strategic substitutability in startup activity and IPO entry but does not introduce a wedge between the private and the social returns and hence it does not change our welfare analysis.

**Other related literature.** Our paper adds to a literature that studies the welfare implications of combining strategic interactions and informational externalities (Vives, 1997, 2017, Angeletos and Pavan, 2009, Amador and Weill, 2010, 2012). While these are typically treated as separate features, in our setting they are tied together: the strategic complementarity is itself the product of an informational spillover.

Related in this regard are Benhabib, Wang and Wen (2015), Chahrour and Gaballo (2020), Gaballo (2018), and Goldstein, Ozdenoren and Yuan (2011). Common to all these papers and ours is the presence of a signal extraction problem that gives rise to some type of strategic complementarity. These papers, however, study different contexts than ours and do not contain the specific mechanism identified here.

---

4It is also worth clarifying that our mechanism allows but does not require strategic uncertainty among the entrepreneurs: the key is that the latter collectively shape IPO prices, not that they face uncertainty about one another's behavior.

5Benhabib et al. (2015) focus on sunspot fluctuations that can be sustained when firms confuse the sunspot with idiosyncratic demand shocks. Chahrour and Gaballo (2020) show how the confusion between idiosyncratic wealth shocks and aggregate housing supply shocks can support equilibria where, unlike the textbook model, supply shocks generate positive co-movement between prices and quantity. Gaballo (2018) revisits Lucas (1973), shows how large private uncertainty may result from small
At a broad level, our paper adds to the study of the nexus between asset prices and real investment. First, we borrow from macro-finance at large the feedback from asset markets to investment, but we add to it an informational feedback of the opposite direction. Second, we connect to the literature on speculation (Harrison and Kreps, 1978), but we let speculative motives operate in startup activity as opposed to financial trading. Third, we complement a literature that studies how the information contained in asset prices helps guide real investment (Dow and Gorton, 1997, Subrahmanyam and Titman, 1999, 2001) by studying the opposite informational spillover, from real investment to asset prices.

Related are also Albagli, Hellwig and Tsyvinski (2017), which focuses on how information heterogeneity among traders impinge on financial market efficiency and thereby on firms’ decisions, and Chari and Kehoe (2003) and Loisel, Pommeret and Portier (2012), which let an informational spillover—in the form of herding—generate “hot money” phenomena. None of these papers, however, features either the two-way feedback at the core of our model or the type of inefficiency discussed above.

Last but not least, our modeling of startup decisions, and in particular their dependence on anticipated IPO returns, connects our work to the literature on short-termism in entrepreneurial decision making (e.g., Bebchuck and Stole, 1993). There are, however, important differences. In our model, the entrepreneurs’ concern with the financial market’s evaluation of their project is fully warranted from a normative standpoint because the reliance on the financial market is essential to the capital expansion that follows the launch of the firms. In this sense, short-termism is not a source of value destruction. What creates an inefficiency in our model is the fact that the collective signaling from the real sector to the financial market introduces a speculative motive that distorts the entrepreneurs’ early decisions along with the information externality that such collective signaling induces on the firms’ subsequent expansions.

**Layout.** The rest of the paper is organized as follows. Section 2 introduces the model. Section 3 characterizes the equilibrium. Section 4 derives the main positive lesson. Section 5 formulates an appropriate efficiency benchmark and derives our policy implications. Section 6 discusses the robustness of our findings. Section 7 concludes by circling back to the literature on IPO waves and discussing possible venues for empirical work. All proofs are in the Appendix at the end of the document.

## 2 Model

There is a single perishable good, which can be used for either consumption or investment. There are three periods $t \in \{1, 2, 3\}$. There are two types of agents, entrepreneurs and investors, each of measure one. Entrepreneurs are born at $t = 1$, investors at $t = 2$. At $t = 1$, the entrepreneurs have the option to start new projects using internal funds, which can also be interpreted as funds provided by an un-modeled venture.

---

\*primitive heterogeneity when firms learn from prices, and uses this kind of near-discontinuity to argue that a small amount of uncertainty in fundamentals can rationalize a large degree of monetary non-neutrality. Finally, in work that was concurrent to the original version of our paper, Goldstein, Ozdenoren and Yuan (2011) study a currency-attack setting where the speculators’ actions become strategic complements when the central bank interprets a greater aggregate attack as a signal of poor economic fundamentals. At the abstract level, the last paper’s mechanism is the closest to ours. However, both the context and the lessons are very different.
capitalist. We refer to this period as the “startup stage.” At \( t = 2 \), those entrepreneurs who started a project at \( t = 1 \) can expand it by selling shares to outside investors and using these funds to make an additional investment. We refer to this period as the “IPO stage.” At \( t = 3 \) (“the longer run”), the projects’ profits are realized and distributed to the entrepreneurs and the outside investors.

**Technology.** Starting a project requires an initial fixed investment of one unit of the perishable good at \( t = 1 \). Once a project is started at \( t = 1 \), it requires an additional investment at \( t = 2 \). The size of this investment can vary. We denote by \( k_i \in \mathbb{R}_+ \) the stage-2 investment of entrepreneur \( i \). At \( t = 3 \), the output of an entrepreneur who started the project at \( t = 1 \) and invested \( k_i \) at \( t = 2 \) is equal to

\[
q_i = \Theta f(k_i),
\]

where \( f(k) = k^\alpha \), with \( \alpha \in (0, 1) \) parametrizing the project’s returns to scale. The profitability of all projects depends on the realization of the aggregate random variable \( \Theta \), which we interpret as the underlying “fundamental”.

**Timing.** Before any agent moves, Nature draws the fundamental \( \theta \equiv \log \Theta \) from a Normal distribution with mean 0 and variance \( \sigma^2_{\theta} = 1/\pi_\theta \). This distribution defines the common prior about \( \theta \), with \( \pi_\theta \) parameterizing the precision of the prior. In addition, Nature draws a variety of private signals, some for the entrepreneurs and some for the investors; we specify the details of these signals in the sequel.

**Startup stage.** At \( t = 1 \), each entrepreneur is endowed with one unit of the perishable good, which he can either consume or invest into a startup. Let \( n_i \in \{0, 1\} \) denote entrepreneur \( i \)'s decision to start a project. We refer to the entrepreneurs who decide to start a project at \( t = 1 \) as “active,” and the rest as “inactive”. Let \( N \) denote the measure of active entrepreneurs and, with some abuse of notation, let \( [0, N] \) denote the set of active entrepreneurs.\(^6\)

**IPO stage.** At \( t = 2 \), the entire profile \((n_i)_{i \in \{0, 1\}}\) of startup decisions is publicly observed. Inactive entrepreneurs have no other source of income and take no further actions.\(^7\) Active entrepreneurs have no income at \( t = 2 \), so their investment \( k_i \) must be fully financed by outside investors. In particular, entrepreneurs finance their investment by selling shares in the IPO market implying that

\[
k_i = p_i s_i, \tag{1}
\]

where \( s_i \in [0, 1] \) is the amount of shares sold by entrepreneur \( i \) and \( p_i \) the price of such shares. The microstructure of the IPO market is described below.

At \( t = 3 \), the fundamental \( \theta \) is publicly revealed and the output of all projects is realized. Each active entrepreneur receives \((1 - s_i)\Theta f(k_i)\) whereas outside investors receive \( s_i \Theta f(k_i) \) from their investment in entrepreneur \( i \)'s project.

---

\(^6\)This amounts to a state-dependent re-ordering of the identities of the entrepreneurs so that the active ones are always listed first.

\(^7\)We studied the implications of relaxing such an assumption in an earlier version of the paper, Angeletos, Lorenzoni and Pavan (2007), albeit under a simplified version of the model.
**Payoffs.** The lifetime utility of entrepreneur $i$ is $U_i = c_{i1} + \beta c_{i2} + \beta^2 c_{i3}$, where $\beta \in (0, 1)$ is the common discount factor. His consumption at $t = 1$ is $c_{i1} = 1 - n_i$, i.e., it is equal to the initial endowment of the perishable good if the entrepreneur does not start a project and is 0 otherwise. At $t = 2$, each entrepreneur's consumption is equal to 0. At $t = 3$, entrepreneur $i$'s consumption is equal to 0 if he did not start a project and is equal to $c_{i3} = (1 - s_i)\Theta f(k_i)$ otherwise. Combining the elements above, we have that the entrepreneur's lifetime utility is equal to

$$U_i = 1 - n_i + n_i \beta^2 \Pi_i,$$

where $\Pi_i \equiv (1 - s_i)\Theta f(k_i)$. (2)

All investors are identical, they behave as price takers, and are symmetrically informed. We thus represent this class of agents with a representative investor. For simplicity, we assume that the supply of funds in the IPO market is perfectly elastic, which can be micro-founded as follows. At $t = 2$, the representative investor can produce the consumption good out of labor effort at a one-to-one rate. The representative investor's consumption levels at $t = 2$ and $t = 3$, respectively, are thus equal to

$$c_2 = l - \int_{i \in [0, N]} p_i s_i di \quad \text{and} \quad c_3 = \int_{i \in [0, N]} s_i \Theta f(k_i) di,$$

where $l$ denotes the investor's labor effort at $t = 2$ and where $s_i$ denotes the quantity of shares bought from active entrepreneur $i \in [0, N]$. The investor's disutility of effort is linear so that his lifetime utility (from period 2's perspective), $V = c_2 - l + \beta c_3$, can be expressed as follows

$$V = \int_{i \in [0, N]} \left[ \beta \Theta f(k_i) - p_i \right] s_i di.$$

The above assumptions imply that the supply of external funds to each active entrepreneur is perfectly elastic at a price equal to the expected profit of the entrepreneur's project. In Section 6, we discuss the robustness of the results to the possibility of an imperfectly elastic supply of funds.

**Information.** At $t = 1$, when choosing whether or not to start a project, each entrepreneur has access to various sources of information (signals) that are not directly available to the investors. The noise in some of these signals may be mostly idiosyncratic, while, for other signals, the noise may be correlated across entrepreneurs. We capture such a possibility in the simplest possible way by assuming that each entrepreneur observes two signals. One has purely idiosyncratic noise and is given by $x_i = \theta + \xi_i$, with each $\xi_i$ drawn from a Normal distribution with mean zero and variance $1/\pi_x$, independently of $\theta$ and independently across entrepreneurs. The other signal is given by $y = \theta + \epsilon$, and its noise $\epsilon$ is perfectly correlated among the entrepreneurs and drawn from a Normal distribution with mean zero and variance $1/\pi_y$, independently from $\theta$ and $(\xi_i)_{i \in [0,1]}$.

As we show below, the key role of the correlated noise $\epsilon$ is to introduce a source of co-movement in startup activity, financial prices, and period-2 investment that can be interpreted as a rational form of "market sentiment" or "exuberance." Such a correlated noise can have various origins. It could originate in the entrepreneurs (a) attending common industry events such as fairs, forums and other networking venues (Ozgen and Baron, 2007), (b) being on a common social network (Robinson and Stubberud, 2011),
or (c) sharing common venture capitalists or “angel investors” (Gompers and Lerner, 1997, Hochberg, Ljungqvist and Lu, 2007). Alternatively, one could embrace a behavioral interpretation of the model in which $y$ is recasted as a biased signal or a taste shock.\(^8\)^9

At $t = 2$, the representative investor receives information about the fundamental $\theta$ which is not directly observed by the entrepreneurs and which is summarized in a private signal $\omega = \theta + \eta$, where $\eta$ is drawn from a Normal distribution with mean zero and variance $1/\pi_\omega$, independently of $\theta$, $\epsilon$ and $(\xi_i)_{i \in [0,1]}$.\(^10\) It follows that the information set with which the representative investor enters the IPO markets in period 2 is given by $\mathcal{I} = \{\omega, (n_j)_{j \in [0,1]}\}$, whereas the corresponding information set of each active entrepreneur $i$ is given by $\mathcal{I}_i = \{x_i, y, (n_j)_{j \in [0,1]}\}$. The information sets with which these agents exit the IPO markets contain, in addition to the above signals, the prices, the shares, and the associated levels of investment in each of the IPO markets: that is, $\mathcal{I}' = \mathcal{I} \cup \mathcal{M}$ and $\mathcal{I}_i' = \mathcal{I}_i \cup \mathcal{M}_i$, where $\mathcal{M} = \{(p_i, s_i, k_i)_{i \in [0,N]}\}$ represents the information generated in the IPO markets.

**IPO market structure.** The IPO market operates in a similar fashion as in Vives (2011, 2017).\(^11\) Each entrepreneur $i$ submits a supply correspondence $S^s_i((\tilde{p}_j)_{j \in [0,N]}, (\tilde{k}_j)_{j \in [0,N]}|\mathcal{I}_i)$, representing the amount of shares he is willing to sell at each price $\tilde{p}_i$, given the prices $(\tilde{p}_j)_{j \in [0,N]}\setminus i$ and investment levels $(\tilde{k}_j)_{j \in [0,N]}\setminus i$ in the other IPOs. The representative investor submits a collection of demand correspondences $\bigl( S^d_i((\mathcal{I})_{i \in [0,N]}\setminus i), (\tilde{k}_j)_{j \in [0,N]}|\mathcal{I}_i)_{i \in [0,N]}\setminus i$, one for each IPO market $i \in [0,N]$, with each $S^d_i((\tilde{p}_j)_{j \in [0,N]}\setminus i, (\tilde{k}_j)_{j \in [0,N]}|\mathcal{I})$ specifying the amount of firm $i$'s shares he is willing to purchase at each price $\tilde{p}_i$, given firm $i$’s investment $\tilde{k}_i$, and given the prices and investment levels $(\tilde{p}_j)_{j \in [0,N]}\setminus i$ and $(\tilde{k}_j)_{j \in [0,N]}\setminus i$ in the other IPO markets.\(^12\) The auctioneer then selects a collection of triples $(p_i, s_i, k_i)_{i \in [0,N]}$, one for each IPO market $i \in [0,N]$, such that each IPO market clears. That is, for each market $i \in [0,N]$,

\[
s_i \in S^d_i((\tilde{p}_j)_{j \in [0,N]}\setminus i, (\tilde{k}_j)_{j \in [0,N]}\setminus i|\mathcal{I}_i) \quad \text{and} \quad s_i \in S^d_i((\tilde{p}_j)_{j \in [0,N]}\setminus i, (\tilde{k}_j)_{j \in [0,N]}|\mathcal{I}), \quad (4)
\]

and each investment $k_i$ is consistent with the price $p_i$ and shares $s_i$ issued, that is,

\[
k_i = p_i \cdot s_i. \quad (5)
\]

By allowing the orders to be contingent on prices, the above structure allows the information of all market participants to be potentially revealed and used by other market participants. This is reminiscent

\(^8\)For example, entrepreneurs in a given industry may come from experiences in a different industry. This may lead them to interpret preliminary data on the viability of a new technology using the same frame of reference.

\(^9\)Finally, as emphasized for example in Hellwig and Veldkamp (2009), strategic complementarities—like the ones that, as we will show below, emerge endogenously in our economy—by themselves generate an incentive for the entrepreneurs to learn from common sources of information or to rely on the same venture capitalists and consultants. See also Dow, Goldstein, and Guembel (2017), Froot, Scharfstein, and Stein (1992), and Veldkamp (2006) for complementary justifications.

\(^10\)While $\omega$ is modeled here as an exogenous signal, it is straightforward to recast it as the outcome of the aggregation of information that may take place in the financial market when the investors themselves have dispersed private information about $\theta$.

\(^11\)See also Malamud and Rostek (2017).

\(^12\)The conditioning of the schedules on the information sets $\mathcal{I}_i$ and $\mathcal{I}$ is mean to highlight that the submitted schedules depend on the entrepreneurs' and the investors' information at the beginning of the IPO stage.
of Grossman and Stiglitz (1980). However, here there is a continuum of assets and a continuum of markets, one for each active project $i \in [0, N]$. Furthermore, the dividend of each such asset is endogenous to the level of capital raised by the respective entrepreneur through the IPO, a property that both the entrepreneurs and the investors understand.

**Equilibrium definition.** An equilibrium is a collection of startup rules $(n_i(\cdot))_{i \in [0, 1]}$, demand and supply correspondences $(S_d^i(\cdot|\cdot))_{i \in [0, N]}$ and $(S_s^i(\cdot|\cdot))_{i \in [0, N]}$, and market outcomes $(p_i(\cdot), s_i(\cdot), k_i(\cdot))_{i \in [0, N]}$ that jointly satisfy the following five conditions:

(i) For each $\mathcal{J}_i$, the supply correspondence $S_s^i(\cdot|\mathcal{J}_i)$ of each active entrepreneur $i \in [0, N]$ maximizes the entrepreneur’s expectation of $\Pi_i$, as in (2), given the entrepreneur’s information $\mathcal{J}_i$.

(ii) For each $\mathcal{J}_i$, the investor’s demand correspondences $(S_d^i(\cdot|\mathcal{J}_i))_{i \in [0, N]}$ maximize the investor’s expectation of $V$, as in (3), given the investor’s information $\mathcal{J}_i$.

(iii) In each state of Nature $(\theta, \varepsilon, \eta, (\xi_i)_{i \in [0, 1]})$, given the submitted demand and supply correspondences $(S_d^i(\cdot|\mathcal{J}_i))_{i \in [0, N]}$ and $(S_s^i(\cdot|\mathcal{J}_i))_{i \in [0, N]}$, the prices, shares, and investments $(p_i, s_i, k_i)_{i \in [0, N]}$ selected by the auctioneer clear all markets and are budget feasible, that is, satisfy conditions (4) and (5).

(iv) For any $(x_i, y)$, each entrepreneur’s startup decision $n_i(x_i, y)$ maximizes the entrepreneur’s expectation of $U_i$.

(v) Expectations are rational.

In short, we study rational expectations equilibria. But we also require that such equilibria satisfy the following three, relatively standard, refinements:

(vi) The equilibrium price in any given IPO market does not reveal any information not contained in the supply and demand schedules submitted by the relevant agents. This restriction is standard and requires the auctioneer to only use information coming from the submitted demand and supply schedules in choosing the outcome $(p_i, s_i, k_i)$ in each market.

(vii) Each entrepreneur $i$ is “informationally small.” In particular, we require that the representative investor’s posterior beliefs about $\theta$ be independent of the startup decision $n_i$ of any individual entrepreneur and of the outcome $(p_i, s_i, k_i)$ of the entrepreneur’s IPO. We allow the investor’s beliefs to be influenced by the distribution $(n_i)_{i \in [0, 1]}$ of startup decisions and the distribution $(p_i, s_i, k_i)_{i \in [0, N]}$ of IPO market outcomes, and of course we allow any given entrepreneur to affect the outcome $(p_i, s_i, k_i)$ of his own IPO via his choice of a supply schedule. What we rule out is only the possibility that the actions of a single entrepreneur move the representative investor’s posterior beliefs about the aggregate fundamental $\theta$.

(viii) The representative investor’s posterior about the aggregate fundamental $\Theta$ is log-normal. Specifically, given $\mathcal{J}$, $\theta$ is normally distributed with a variance that is state-invariant; and the investor’s
posterior mean about $\theta$, denoted by $\hat{\theta} \equiv \mathbb{E}[\theta | I]$, is normally distributed with a variance that is invariant in $I$. This restriction is also standard and is made for tractability, as it allows us to solve for the entrepreneurs’ and the investor’s inference problems in closed form.

3 Equilibrium Characterization

We characterize the equilibrium in four steps. First, we show how the investor’s information determines share prices and investment levels in the IPO market. Second, we show how the entrepreneurs’ expectations of share prices and fundamentals determine their startup decisions. Third, we show how aggregate startup activity conveys to the investor some of the entrepreneurs’ information. In the fourth, and last, step, we close the loop by checking that the investor’s information in the IPO stage is consistent with the endogenous signal contained in the startup activity.

Step 1: IPOs

Let us start from the IPO stage. Let

$$\hat{\Theta} \equiv \mathbb{E}[\Theta|\omega, (n_j)_{j \in [0,1]}, (p_j)_{j \in [0,N]}, (k_j)_{j \in [0,N]}]$$

denote the representative investor’s equilibrium expectation of the fundamental. Because the investor is risk neutral, in equilibrium, it must be that the following relationship holds

$$p_i = \beta \hat{\theta} f(k_i) \quad \text{(6)}$$

in each market $i \in [0, N]$.

Now consider the problem of each active entrepreneur. We proceed in two steps. First, we let the entrepreneur solve a relaxed problem. Next, we show that there exists a supply schedule $S^*_i$ that implements the solution to such a problem.

The relaxed problem is one in which the entrepreneur knows $\hat{\Theta}$ and picks $(p_i, s_i, k_i)$ to maximize his payoff subject to (6) and the budget constraint (5). Combining these two conditions, we have that

$$s_i = \frac{k_i}{\beta \hat{\Theta} f(k_i)} \quad \text{(7)}$$

The entrepreneur’s payoff can then be expressed as a function of $\Theta, \hat{\Theta},$ and $k_i$, as follows:

$$(1 - s_i)\Theta f(k_i) = \frac{\Theta}{\beta \hat{\Theta}} \left[ \beta \hat{\Theta} f(k_i) - k_i \right] \quad \text{(8)}$$

Because the entrepreneur is informationally small, he treats $\hat{\Theta}$ as invariant to his choices. As a consequence, the value of $k_i$ that maximizes the right-hand side of (8) is given by

$$K(\hat{\Theta}) \equiv \arg\max_k \{ \beta \hat{\Theta} f(k) - k \} \quad \text{(9)}$$
The corresponding values of $s_i$ and $p_i$ are then given by (7) and (6) respectively. Note that, conditional on $\hat{\Theta}$, the solution $(p_i, s_i, k_i)$ to the relaxed program is thus invariant to any private information entrepreneur $i$ may have.

We now construct the entrepreneur’s supply schedule that implements the above solution. Note that $K(\hat{\Theta})$ is strictly increasing in $\hat{\Theta}$ and that the expression on the right-hand side of (6) is strictly increasing in $k_i$. The following expression then defines a bijective relation between $p_i$ and $\hat{\Theta}$:

$$p_i = P(\hat{\Theta}) = \beta \hat{\Theta} f(K(\hat{\Theta})).$$

Given the above bijective relation, and using the fact that $s_i = k_i / p_i$, we have that the supply schedule that permits the entrepreneur to implement the allocation that solves the relaxed program is equal to

$$S_{s_i}((\hat{p}_j)_{j \in [0,N]}, (\hat{k}_j)_{j \in [0,N] \backslash i} | f_i) = K(P^{-1}(\hat{p}_i)) / \hat{p}_i. \quad (10)$$

We conclude that the equilibrium outcome of each market $i = [0, N]$ is given by

$$(p_i, s_i, k_i) = (P(\hat{\Theta}), K(\hat{\Theta}) / P(\hat{\Theta}), K(\hat{\Theta})).$$

Because the latter are invariant in the entrepreneurs’ private information, the restriction that the equilibrium price in any given IPO market not reveal any information not contained in the supply and demand schedules then implies that necessarily

$$\hat{\Theta} = \mathbb{E}[\Theta|\omega, (n_j)_{j \in [0,1]}] = \mathbb{E}[\Theta|\mathcal{F}].$$

That is, the representative investor does not learn anything about $\Theta$ after observing the prices $(p_j)_{j \in [0,N]}$ and the investments levels $(k_j)_{j \in [0,N]}$. In other words, there is no information revelation at the IPO stage. This is a consequence of the entrepreneurs being cash-less at the IPO stage (an assumption we revisit in Section 6).

Given the Cobb-Douglas technology specification, we can then solve explicitly for the equilibrium investments, prices, and shares:

$$K(\hat{\Theta}) = (\alpha \beta \hat{\Theta})^{1-\alpha}, \quad P(\hat{\Theta}) = \alpha^{1-\alpha} (\beta \hat{\Theta})^{1-\alpha}, \quad S(\hat{\Theta}) = \alpha. \quad (11)$$

Replacing the above into the entrepreneurs’ supply schedules we then obtain that the latter are equal to

$$S_{s_i}^*(((\hat{p}_j)_{j \in [0,N]}, (\hat{k}_j)_{j \in [0,N] \backslash i} | f_i) = \alpha$$

for all $(\hat{p}_j)_{j \in [0,N]}, (\hat{k}_j)_{j \in [0,N] \backslash i}$ and no matter $f_i$. That the amount of shares traded in equilibrium is equal to $\alpha$ in each state implies that, even though we have allowed entrepreneurs to post contingent supply schedules (aka generalized limit orders), the same equilibrium prices and allocations obtain if we assume a different market micro-structure whereby entrepreneurs commit to sell a fixed quantity of shares independently of the price (aka market orders).
Step 2: Startup stage

We now proceed to characterize the equilibrium outcomes in the startup stage. From (2), entrepreneur $i$ finds it optimal to start the project if, and only if,

$$
\beta^2 E_i[\Pi_i] \geq 1, \quad (12)
$$

where $E_i[\cdot]$ is a shortcut for $E[\cdot|x_i, y]$ and where $\Pi_i \equiv (1 - s_i)\Theta f(k_i)$. Using (11), we can express the realized profit $\Pi_i$ as a function of $\Theta$ and $\hat{\Theta}$, as follows:

$$
\Pi_i = \Pi(\Theta, \hat{\Theta}) \equiv (1 - \alpha)\Theta f(K(\hat{\Theta})) = (1 - \alpha)\Theta(a\hat{\Theta}) = (1 - \alpha)(1 - \alpha\hat{\Theta}), \quad (13)
$$

We now use the restrictions that $\hat{\theta} \equiv E[\theta|\mathcal{I}]$ and $\theta|\mathcal{I}$ are normally distributed with deterministic variances.\(^\text{13}\) As we show in the Appendix (proof of Proposition 1), these restrictions imply that entrepreneur $i$ finds it optimal to start a project if and only if

$$
E_i[(1 - \alpha)\theta + a\hat{\theta}] \geq C, \quad (14)
$$

where $C$ is a scalar determined in equilibrium. Notice that to derive this condition we are also using the restriction that each entrepreneur is informationally small, that is, that the representative investor’s information $\mathcal{I}$ is independent of entrepreneur $i$’s individual startup decision.

Condition (14) captures the first direction of the feedback mechanism at the core of our paper: when entrepreneurs expect a higher market valuation, they have a higher incentive to start a project. In particular, Condition (14) shows that it is optimal for an entrepreneur to start a project if and only if he is sufficiently optimistic about a weighted average of the fundamental and of the market’s valuation of profitability. The intuition behind this condition is simple. The entrepreneur’s decision depends on his expectation of $\theta$ because the latter directly affects his project’s output. The entrepreneur’s decision depends on his expectation of the market’s valuation $\hat{\theta}$ because that variable determines the cost of raising capital in the IPO market: the higher $\hat{\theta}$ is, the higher the IPO stock price, and hence the higher the amount of capital that the entrepreneur raises and invests at the IPO stage.

The relative importance of $\theta$ and $\hat{\theta}$ is determined by $\alpha$, which reflects the strength of the decreasing returns to the period-2 investment. A higher $\alpha$ implies that profits are more sensitive to the entrepreneur’s capacity to raise capital in the IPO stage and hence that they are more sensitive to variations in share prices.

Given that $\theta$, $\hat{\theta}$ and the available signals are jointly normal, condition (14) is equivalent to

$$
(1 - b)x_i + by \geq c, \quad (15)
$$

for some constants $b$ and $c$ to be determined. This condition gives us the entrepreneur’s strategy in the startup stage, that is, it characterizes the startup decision as a function of the entrepreneur’s information.

\(^{13}\)It may be useful to clarify that $\hat{\theta} \equiv E[\theta|\mathcal{I}]$ is different from $\log\hat{\Theta}$, where $\hat{\Theta} \equiv E[\Theta|\mathcal{I}]$. The two differ by a constant that is derived in the Appendix.
Using (15) we can derive the aggregate level of startup activity:

\[ N = \Pr \left( (1-b)x_i + by \geq c \mid \theta, y \right) = \Phi \left( \frac{\sqrt{\pi_x (1-b)\theta + by - c}}{1-b} \right), \tag{16} \]

where \( \Phi \) is the standard-normal cumulative distribution function. The second equality follows from the definitions of the signal \( x_i \) and from the symmetry of the normal distribution. Because strategies, and hence the scalars \( b \) and \( c \), are commonly known in equilibrium, the above implies that the observation of \( N \) conveys to the representative investor the same information as the signal

\[ z \equiv (1-b)\theta + by = \theta + b\varepsilon. \tag{17} \]

The level of startup activity \( N \) is a noisy indicator of \( \theta \) because the investor cannot tell apart whether, for example, a high value of \( N \) is driven by a high realization of the fundamental \( \theta \) or by a high realization of the correlated noise in the entrepreneurs’ beliefs.

The precision of the signal \( z \) can be derived using the last expression in (17) and is equal to

\[ \pi_z = \pi_y / b^2. \]

This precision is endogenous and depends on the entrepreneurs’ strategy: the signal-to-noise ratio decreases with the coefficient \( b \), which measures the relative response of the entrepreneurs’ start-up decision to the two signals \( x_i \) and \( y \). This is a key property, whose positive and normative implications we study in the sequel.

Note that, under this simple information structure, \( N \) reveals \( \theta \) perfectly to the entrepreneurs. This is a consequence of the assumption that all the correlated noise in the entrepreneurs’ information originates in the common signal \( y \). However, this property, which is not important to our results, does not extend to richer information structures, for example, by adding idiosyncratic noise to the entrepreneurs’ observations of \( y \).

Step 3: Market valuation

We now derive the investors’ valuations when entering the IPO market. Investors have two sources of information, the exogenous signal \( \omega \) and the distribution of startup decisions \( (n_j)_{j \in [0,1]} \). The restriction that individual startup decisions do not have a direct effect on the investor’s expectation of \( \Theta \) implies that \( (n_j)_{j \in [0,1]} \) contains the same information as \( N \). We thus have that

\[ \hat{\Theta} = \mathbb{E}[\Theta \mid \mathcal{F}] = \mathbb{E}[\Theta \mid \omega, N]. \]

This condition captures the second direction of our feedback mechanism: a high level of startup activity increases the market’s valuation of firms’ profitability at the IPO stage. Using the fact that the information in \( N \) is equivalent to the information in \( z \), we can verify that the equilibrium we are constructing satisfies our distributional restrictions on \( \theta \) and \( \hat{\theta} \). First, we verify that \( \theta \mid \mathcal{F} \) is normally distributed with mean

\[ \hat{\theta} = \mathbb{E}[\theta \mid z, \omega] = \frac{\pi_x}{\pi} \omega + \frac{\pi_z}{\pi} z, \tag{18} \]
and (state-invariant) variance $1/\pi$, where $\pi = \pi_\theta + \pi_\omega + \pi_z$ is the posterior precision, as assumed. Second, using (18), we verify that $\hat{\theta}$ is normally distributed with a variance that is state-invariant, as assumed.

**Step 4: Fixed point**

Now that we have an explicit expression for the investors’ valuation $\hat{\theta}$ we can go back to the entrepreneurs’ optimality condition (14) and use it to derive explicitly the coefficients defining their start-up decisions, as assumed in (15).

Given (17) and (18), each entrepreneur’s forecast of $\hat{\theta}$ is given by

$$E_i[\hat{\theta}] = \pi_\omega + \pi_z (1 - b) \pi_{\theta} + \pi_z b y.$$  \hspace{1cm} (19)

Bayesian updating implies that

$$E_i[\theta] = \delta_x x_i + \delta_y y$$ \hspace{1cm} (20)

where

$$\delta_x = \frac{\pi_x}{\pi_\theta + \pi_x + \pi_y} \quad \text{and} \quad \delta_y = \frac{\pi_y}{\pi_\theta + \pi_x + \pi_y}.$$  

Substituting $\delta_x$ and $\delta_y$ into (19) we then obtain that each entrepreneur finds it optimal to start a project if, and only if,

$$(1 - b') x_i + b' y \geq c'$$  \hspace{1cm} (21)

where the coefficients $b'$ and $c'$ depend only on $b$ and exogenous parameters (see the Appendix for the details). So the problem of finding an equilibrium boils down to finding a fixed point to a known function $\Gamma$ that maps $b \in \mathbb{R}$ to some $b' \in \mathbb{R}$. This function, which is defined explicitly in the Appendix, has a simple interpretation: when the investors believe that the distribution of start-up decisions contains the same information as the signal $z = \theta + b \epsilon$, for some $b \in \mathbb{R}$, the entrepreneurs respond by following a start-up rule that amounts to sending to the investors a signal $z' = \theta + b' \epsilon$ with $b' = \Gamma(b)$. In equilibrium the signal received by the investors must coincide with the signal sent by the entrepreneurs. We then have the following result:

**Proposition 1.** There are two functions $\Gamma : \mathbb{R} \rightarrow \mathbb{R}$ and $\Lambda : \mathbb{R} \rightarrow \mathbb{R}$ such that if $b^*$ is a fixed point of $\Gamma$ and $c^* = \Lambda(b^*)$, then there is an equilibrium in which each entrepreneur $i$ starts a project if, and only if,

$$(1 - b^*) x_i + b^* y \geq c^*.$$  \hspace{1cm} (22)

Closed-form expressions for $\Gamma$ and $\Lambda$ are derived in the Appendix. Studying these functions permits us to reach the following existence and uniqueness results:
Proposition 2. (i) There exists an equilibrium in which all entrepreneurs follow the start-up decision rule in (22) with \( b^* \in (0, 1) \). In this equilibrium, startup investment \( N \), the market valuation of profitability \( \hat{\Theta} \), and the share price \( p = P(\hat{\Theta}) \) are all increasing in the fundamental \( \theta \) and in the noise \( \epsilon \). (ii) For any parametrization of the information structure, there exists a cutoff value \( \bar{\alpha} > 0 \) for the capital share in production, such that the equilibrium is unique for all \( \alpha \leq \bar{\alpha} \). (iii) If \( \alpha > \bar{\alpha} \), multiple equilibria are possible.

The intuition for part (i) is as follows. When \( b^* \in (0, 1) \), each entrepreneur’s startup activity responds positively to both signals \( x_i \) and \( y \). This implies that aggregate startup activity responds positively to both the fundamental \( \theta \) and the noise \( \epsilon \). Whenever this is the case, the investors’ expectation of \( \theta \), and by implication the equilibrium asset prices, also respond positively to both \( \theta \) and \( \epsilon \). This is because the investors correctly perceive high aggregate activity as “good news” about profitability, but cannot distinguish between increases in activity driven by \( \theta \) from those driven by \( \epsilon \).

Part (ii) guarantees that the equilibrium is unique if \( \alpha \) is small enough, in which case the sensitivity of startup activity to the expected market valuation is not too high. When, instead, \( \alpha \) is high, multiple equilibria can emerge. The possibility of multiple equilibria does not interfere with the main message of the paper—it only reinforces it by opening the door to sunspot volatility. At the same time, the positive and normative implications of the informational spillovers at the core of our paper are most cleanly isolated by ruling out multiple equilibria. With this in mind, in the sequel we restrict attention to the region of the parameter space that guarantees equilibrium uniqueness.

4 Positive Analysis

In this section we show how our mechanism gives rise to amplification of non-fundamental volatility; discuss the sense in which it represents a form of speculation and a form of beauty contest; and highlight how its potency is likely to be highest in sectors with high growth potential and/or high finance dependence.

Amplification role of information spillovers

To gain more insight, it is worth contrasting the equilibrium outcomes of our economy to variants in which there is no informational spillover from the real sector to the financial sector. To this purpose, suppose that investors do not learn from the observation of \( N \). This could be either because investors do not observe \( N \), or because their exogenous signal \( \omega \) is already perfectly informative of \( \theta \), which obtains when \( \pi_\omega \to \infty \). We consider both cases to emphasize that the positive results in Proposition 3 below do not depend on the amount of information in the investors’ hands. What matters for the result is whether or not investors learn about aggregate profitability by looking at the entrepreneurs’ activity.

When investors do not learn from \( N \), their valuation \( \hat{\theta} \) is just a linear function of their exogenous signal \( \omega = \theta + \eta \). Since entrepreneurs do not possess any information about \( \eta \) at the startup stage, their expectation of \( \hat{\theta} \) is simply a linear transformation of their expectation of the fundamental \( \theta \). It follows that, in the absence of informational spillovers, the entrepreneurs’ start-up Condition (14) reduces to \( E_i[\theta] \geq C \), for
some constant $C$. Using (20), we then have that each entrepreneur starts a project at $t = 1$ if, and only if,

$$(1 - \delta)x_i + \delta y \geq c$$

where $\delta = \delta_y/\delta_x$ and where $c$ is a scalar that depends on all exogenous parameters.

The following result compares the entrepreneurs’ start-up decisions in the model with investment spillovers to their counterparts in the absence of informational spillovers.

**Lemma 1.** In the equilibrium in part (i) of Proposition 2, $b^* > \delta$.

The result shows that the two-way feedback between real activity and financial prices raises the relative sensitivity of the entrepreneurs’ startup activity to the correlated component of their private information, here captured by the signal $y$.

We provide more intuition for this result in the next subsection. First, we look at the aggregate implications of this result for investment and asset price volatility. Recall that, when the entrepreneur follows a strategy of the form in (15), aggregate startup activity is given by

$$N = \Phi\left(\sqrt{\frac{x}{\theta + b\varepsilon - c}}\right).$$

It follows that

$$\frac{\partial N/\partial \varepsilon}{\partial N/\partial \theta} = b.$$  

That is, a higher value of $b$ implies a higher sensitivity of aggregate startup activity to the non-fundamental noise $\varepsilon$ relative to the fundamental $\theta$. By the same token, if an econometrician were to observe data generated by our model and run a regression of aggregate startup activity on the fundamental $\theta$, the R-squared of this regression—which measures the contribution of the fundamental $\theta$ to the volatility of aggregate startup activity—will be smaller the higher $b$ is.\(^{14}\) In what follows, we thus refer to $b$ interchangeably as the sensitivity of the entrepreneurs’ startup activity to $y$ relative to $x$, and as a measure of the contribution of noise to aggregate volatility.

Based on the preceding observations, we reach the following conclusion:

**Proposition 3.** The informational spillovers from the real to the financial sector amplify the contribution of noise to aggregate volatility.

**Mis-pricing and speculation**

Let us rewrite Condition (14), which characterizes the entrepreneurs’ startup decisions, as follows:

$$E_i[\theta] + \alpha E_i[\hat{\theta} - \theta] \geq C.$$  \hspace{1cm} (23)

Recall that $\hat{\theta}$ captures the market valuation of capital during the IPO stage, while $\theta$ identifies the true underlying profitability of capital. Therefore, the gap $\hat{\theta} - \theta$ reflects the log difference between the market

\(^{14}\)To be precise, for a linear regression to be valid, one needs to regress the transformation $\Phi^{-1}(N)$ on $\theta$. 

price of capital and its realized value. Accordingly, we interpret $\hat{\theta} - \theta$ as a measure of the “mis-pricing”, or “pricing error”, that arises in the financial market due to the noise in the available information. Such mis-pricing is consistent with the investors’ rational behavior. The investors are fully aware of it but there is nothing they can do to correct it given their available information.

Condition (23) then says that the decision of each entrepreneur to start a project depends, not only on his forecast of the underlying fundamental profitability of the project, but also on his forecast of the pricing error. This is because a higher pricing error in the IPO stage translates into a lower cost of raising capital and, therefore, to a higher profit for the entrepreneur. In this sense, the term $\hat{\theta} - \theta$ in (23) also captures a form of speculation that is reminiscent of the dot-com bubble: a higher startup activity obtains when entrepreneurs expect financial markets to overvalue their businesses.

The result that $b^* > \delta$ can then be interpreted as follows. Recall that the representative investor’s forecast of $\theta$ is $\hat{\theta} = \frac{\pi_\omega}{\pi} \omega + \frac{\pi_z}{\pi} z$, where $z = \theta + b^* \epsilon$ is the endogenous signal contained in the aggregate startup activity. To simplify, consider the limit case of an uninformative prior, which corresponds to $\pi_\theta \to 0$. In this case, $\frac{\pi_\omega}{\pi} + \frac{\pi_z}{\pi} = 1$, which implies that the pricing error can be rewritten as

$$\hat{\theta} - \theta = \frac{\pi_\omega}{\pi} \eta + \frac{\pi_z}{\pi} b^* \epsilon,$$

where $\eta$ is the noise in the investor’s exogenous signal $\omega$, whereas $b^* \epsilon$ is the noise in the endogenous signal $z$. A high value of the common noise $\epsilon$ in the entrepreneurs’ signals then leads to a high level of startup activity, which is perceived by the investors as a favorable signal of underlying profitability $\theta$ thus leading to overpricing.

Now consider the entrepreneurs’ decision at the startup stage. The entrepreneurs receive no information about $\eta$, so their expectation of $\eta$ is zero. On the other hand, they possess information about $\epsilon$ through their correlated signal $y$. Their expectation of $\epsilon$ is given by

$$\mathbb{E}_i[\epsilon] = y - \mathbb{E}_i[\theta] = (1 - \delta_y) y - \delta_x x_i.$$ 

The $y$ signal contains information both about $\theta$ and about $\epsilon$. A high value of $y$ thus contributes positively to the entrepreneurs’ expectation of both the primitive profitability $\theta$ of their startup activity and of the pricing error at the IPO stage. By contrast, a high value of $x_i$ contributes positively to the entrepreneurs’ expectation of $\theta$ but negatively to their expectation of the pricing error. This explains why, in equilibrium, $b^* > \delta$, that is, the relative sensitivity of the entrepreneurs’ startup activity to sources of information with correlated noise is higher than what warranted by the relative informativeness of such sources vis-a-vis the fundamental.

The argument above uses the specific signal structure assumed here. The result, however, is more general. When an entrepreneur is idiosyncratically optimistic about the profitability of his project (which is the case here when $x_i$ is high relative to $y$), he expects the financial market to receive only a modest signal from the aggregate startup activity and hence the cost of raising capital to be relatively high, which dampens his incentive to start the project. By contrast, when the entrepreneurs are collectively optimistic about the profitability of their projects (which is the case here when $y$ is high), they expect the financial
market to receive a strong positive signal from aggregate startup activity and thereby the IPO prices to be high, which boosts their incentives to start a project. It is this spillover from the collective optimism of the entrepreneurs to the exuberance of the financial markets that crowds out private information and amplifies non-fundamental volatility.

Notice that the mere fact that the equilibrium startup activity responds to the expectation of financial prices is not per se a symptom of inefficiency. To the extent that the cost of financing (and, related, the social cost of expanding the existing projects) depend on the market valuation \( \hat{\theta} \), there are efficiency gains from having the initial startup decision respond to expectations of market valuation. We postpone addressing the efficiency properties of the equilibrium to Section 5.

### A beauty contest interpretation

We now offer an alternative interpretation of our result, which builds a bridge to the literature on “beauty contests” (see, among others, Morris and Shin, 2002, and Allen, Morris and Shin, 2006).

Recall that the market valuation \( \hat{\theta} \) is a linear function of the endogenous signal \( z \) that the real sector sends to the financial market, and that this signal is itself a monotone transformation of the aggregate startup activity \( N \). Using these facts, we can express the expected payoff of starting a project as a monotone function of \( \theta \) and \( N \), which yields the following result:

**Proposition 4.** There exists scalars \( r, c^\# > 0 \) such that, in equilibrium, each entrepreneur starts a project if, and only if,

\[
\mathbb{E}_i[(1 - r)\theta + r\Phi^{-1}(N)] \geq c^\#.
\]

The equilibrium startup activity in our model can therefore be represented as the PBE of a binary-action coordination game among the entrepreneurs in which the best response is given by (24). This best response is akin to the best response function in the beauty contest games studied by, inter alia, Morris and Shin (2002), and Angeletos and Pavan (2007). It follows that the amplified effect of the \( y \) signal on non-fundamental volatility in our model is akin to the amplified effect of public information in those games: in both cases, the amplification effect can be traced to strategic complementarity.

What distinguishes our framework from this other work is that the strategic complementarity is here endogenous, originating in the information spillovers from the real to the financial sector. Although each entrepreneur alone is too small to have any impact on either aggregate startup activity or on the investors’ beliefs, the entrepreneurs as a group can influence the investors’ beliefs and hence the price in the financial market. This leads to a complementarity in the entrepreneurs’ actions: the higher the aggregate startup activity, the higher the market valuation of the new projects, and hence the lower the cost of raising capital at the IPO stage. This explains why strategic complementarity in the entrepreneurs’ decisions (i.e., \( r > 0 \)) emerges whenever a high aggregate level of startup activity is interpreted by the financial maker as “good news”. By contrast, strategic complementarity vanishes (i.e., \( r = 0 \)) when the financial market does not extract any information from the real sector’s activity, as in the benchmark without spillovers considered above.
In Section 5, we explain that this type of complementarity represents a form of inefficiency. This is in contrast to the efficient beauty contest that emerges from aggregate demand externalities in the textbook business-cycle paradigm (Angeletos and La’O, 2010, 2020) or, more generally, from the kind of strategic complementarities or substitutabilities that emerge from pecuniary externalities in the Arrow-Debreu framework. Importantly, our mechanism remains the only source of inefficiency even when such neoclassical effects are added to the analysis (see Section 6). Finally, because starting a project is linked to doing an IPO, the strategic complementarities identified above square well with the “hot IPO effect” mentioned in the Introduction.

The impact of $\alpha$

So far we have shown that informational spillovers lead to the amplification of non-fundamental shocks. We now show that the strength of these effects depends on the parameter $\alpha$. The parameter $\alpha$ plays a double role in our model: it captures the growth potential of the real sector, as a larger $\alpha$ means a lower degree of decreasing returns; it also captures the real sector’s dependence on funding from the financial market, as a larger $\alpha$ implies that the entrepreneurs’ period-2 investments $k$ are more sensitive to financial market valuations. In equilibrium, a larger value of $\alpha$ increases the entrepreneurs’ incentives to rely on the correlated signal $y$ to predict the mis-pricing in the IPO stage. Formally, a higher value of $\alpha$ shifts the $\Gamma$ function in Proposition 1 upwards. As long as $\Gamma$ admits a unique fixed point ($\alpha < \bar{\alpha}$), this implies a higher sensitivity $b^*$ of the entrepreneurs’ startup activity to sources of information with correlated noise. We thus have the following result:

**Proposition 5.** A higher value of $\alpha$ implies a higher contribution of correlated noise to aggregate volatility—but only through the information spillover.

Our theory thus predicts that sectors with high growth potential and/or high finance dependence are those most prone to non-fundamental volatility and our kind of strategic complementarity (“hot IPO effect”) and that this effect is especially salient in the early stages of a new sector’s life, when there is still significant uncertainty about its eventual profitability (small $\pi_0$). The prediction seems consistent with historical experiences such as the dot-com bubble as well as the evidence reported in Jain and Kini (2006) that IPO clustering tends to occur in fragmented, high growth, R&D-intensive industries.

5 Normative Analysis and Policy

The analysis in the previous section focuses on the positive properties of the equilibrium and shows that information spillovers increase the contribution of correlated noise to non-fundamental volatility of startup activity, IPO prices, and capital investments. We now turn to the normative implications of the mechanism identified above. The questions that we address are the following: Are the positive properties

---

15Relaxing the restriction that $\alpha < \bar{\alpha}$ only reinforces the result in Proposition 5 by adding sunspot volatility.
derived so far a symptom of inefficiency? And, if so, how should policy influence entrepreneurial decisions? To address these questions, we proceed in two steps. We start by studying the problem of a social planner who can dictate to the entrepreneurs the strategy that they should follow at the startup stage. This planning problem bypasses the details of the available policy instruments and identifies directly the normative content of the aforementioned positive properties. Once the solution to the planner’s problem is at hands, we discuss policies that implement the planner’s optimum as well as policies that, while not the ideal ones within our model, have received attention in the policy debate.

5.1 Constrained Efficiency

Consider a social planner who can choose a linear startup rule of the form

\[ n_i = 1 \quad \text{if and only if} \quad (1 - b)x_i + by \geq c, \]  

for some scalars \( b, c \in \mathbb{R} \) and can choose investment \( k_i \) in period 2 as a function of the signal \( \omega \) of the representative investor and of aggregate startup activity \( N \). By setting up the planner’s problem this way, we constrain the planner to use the same information as the market economy. Requiring linearity of the startup rule is a restriction which we make for tractability. Suppose that the planner’s objective is to maximize a utilitarian welfare function assigning equal weights to the entrepreneurs’ and the investors’ utilities. Because of the linearity of individual payoffs in consumption, social welfare is given by the present value of aggregate output, net of all investment costs:

\[
\int_0^1 \{ n_i \left( \beta^2 \Theta f(k_i) - \beta k_i \right) + (1 - n_i) \} \, di = 1 + N \left( \beta^2 \Theta f(k) - \beta k - 1 \right).
\]

Note that in writing the welfare function above we use the fact that, because of concavity of \( f \), it is optimal to dictate the same level of investment to all entrepreneurs who are active in period 2. Given the startup rule (25), aggregate startup activity is given by

\[
N = \Phi \left( \frac{\sqrt{\pi e}}{1 - b} (z - c) \right),
\]

where \( z \) is the endogenous signal \( z = \theta + b \varepsilon \). Since the planner can condition the choice of \( k \) on \( (\omega, N) \), and observing \( N \) is equivalent to observing \( z \), the planner’s problem can be written as

\[
\max_{(b,c) \in \mathbb{R} \times \mathbb{R}, \mathcal{K} \in \mathcal{C}} \mathbb{E} \left[ N(z) \left( \beta^2 \Theta f(\mathcal{K}(\omega, z)) - \beta \mathcal{K}(\omega, z) - 1 \right) \right] \quad \text{s.t.} \quad z = \theta + b \varepsilon, \quad N(z) = \Phi \left( \frac{\sqrt{\pi e}}{1 - b} (z - c) \right),
\]

where \( \mathcal{C} \) denotes the set of continuous functions \( \mathcal{K} : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R} \).

Consider first the choice of \( \mathcal{K} \). For almost every \( (\omega, z) \), \( \mathcal{K}(\omega, z) \) must maximize the expected output net of investment costs:

\[
\mathcal{K}(\omega, z) \in \arg \max_k \{ \beta \Theta f(k) - k \},
\]
where $\hat{\Theta} = E[\Theta|\omega, z]$. Recall that the same maximization problem determines investment in the market equilibrium, therefore,

$$\mathcal{K}(\omega, z) = K(\hat{\Theta}) = (\alpha \beta \hat{\Theta})^{1/\alpha}.$$  

(26)

This proves that the equilibrium level of investment is efficient conditional on the information available to the investors at the IPO stage. Notice, however, that the signal $z$ may be different from the analogous signal in the market equilibrium, if the planner chooses a different startup strategy, reflecting the informational externality that aggregate startup activity exerts on the subsequent capital expansions.

Thus consider next the optimal startup strategy. Given (26), the social value of a project, net of investment costs at $t = 2$, is given by

$$Q(\Theta, \hat{\Theta}) \equiv \beta \Theta f(K(\hat{\Theta})) - K(\hat{\Theta}) = \beta(\Theta - \alpha \hat{\Theta})(\alpha \beta \hat{\Theta})^{\alpha/\alpha - 1}.$$  

The planner’s objective at the startup stage can thus be written as

$$E[n(x, y)\{\beta Q(\Theta, \hat{\Theta}) - 1\}],$$

(27)

where $n(x, y)$ denotes the startup rule (25). The following proposition characterizes the optimal startup rule for the planner.

**Proposition 6.** Let $(b^*, c^*)$ denote the coefficients of the startup rule that maximizes social welfare (27). When the equilibrium is unique (which is always the case for $\alpha < \bar{\alpha}$), $b^* < b^*$, meaning that the equilibrium sensitivity of startup decisions to the signal with correlated noise is too high from a welfare perspective. Consequently, the contribution of correlated noise to aggregate volatility is inefficiently high.

There are two reasons why the planner’s startup rule differs from the market equilibrium one. First, comparing (12) and (27), one can see that the private return to startup activity is $\beta^2 E[\Pi(\Theta, \hat{\Theta})|x, y]$, while the social return is $\beta E[Q(\Theta, \hat{\Theta})|x, y]$. Second, the planner internalizes the fact that different startup rules imply different informativeness of the endogenous signal upon which the subsequent expansions at $t = 2$ are made. The proof of Proposition 6 in the Appendix shows that both forces go in the direction of choosing a smaller $b$. We now discuss the two parts of this argument separately.

First, consider the discrepancy between the private and the social benefit of starting a project. To isolate this effect, consider a planner who can choose the startup rule, but only that of entrepreneur $i$, in which case the information revealed by $N$ continues to be the same as in the market equilibrium. Note that

$$Q(\Theta, \hat{\Theta}) \equiv \beta \Theta f(K(\hat{\Theta})) - K(\hat{\Theta}) =$$

$$= \beta \Pi(\Theta, \hat{\Theta}) + \alpha \beta (\Theta - \hat{\Theta}) f(K(\hat{\Theta})).$$

(28)

The last term in (28) is the difference between the true value of the shares sold to the investors at the IPO (i.e., the associated cash flow) and the investors’ valuation of these shares, given the information available
to them.\(^{16}\) Therefore, as long as the entrepreneur’s expectation \(E[\hat{\Theta}|x, y]\) of the investors’ expectation of \(\Theta\) differs from the entrepreneur’s own expectation \(E[\Theta|x, y]\) of \(\Theta\), the social and private benefits differ:

\[
\beta E(Q(\Theta, \hat{\Theta})|x, y) - \beta^2 E[\Pi(\Theta, \hat{\Theta})|x, y] \neq 0.
\]

This difference is related to the mis-pricing discussed in the previous section. In particular, when the entrepreneur expects \(\hat{\Theta}\) to be higher than \(\Theta\), he expects his shares to be overvalued at the IPO stage, i.e., he expects to make a gain at the expenses of the outside investors. Because this speculative gain is a zero-sum transfer from the investors to the entrepreneur, it does not enter the planner’s objective. As argued in the previous section, a high value of the signal \(y\) relative to \(x\) tends to increase the entrepreneur’s expectation of \(\hat{\Theta}\) relative to \(\Theta\), and thus increases the entrepreneur’s incentive to start the project for speculative reasons. It follows that the planner, who is not driven by speculative motives, would like the entrepreneur to put less weight on \(y\) relative to \(x\), which means a lower \(b\).

Next, consider the informational effects of choosing a smaller value of \(b\), when the planner can choose the startup rule for all entrepreneurs and thus affects the precision of the endogenous signal \(z\) at the IPO stage. The precision of \(z\) is decreasing in \(b\) and more precision is welfare improving, because it increases the efficiency of the second-period investment decisions. Formally, the ex-ante expectation of \(Q(\Theta, \hat{\Theta})\) is increasing in \(\pi_z\). This informational effect adds to the social benefit of reducing \(b\) to mitigate the entrepreneurs’ speculative entry decisions and thus reinforces the conclusion that \(b^\diamond < b^\ast\).

To recap, there are two reasons why the equilibrium sensitivity of startup decisions to the signal with correlated noise is inefficiently high. The first one is that the entrepreneurs can predict the difference between fundamental profitability and its market valuation, and this predictability generates a speculative wedge between their private incentives and social welfare. The second one is that there is an informational externality associated with the endogeneity of the information upon which second-period investment decisions are made. Conceptually, these sources of inefficiency are distinct. In our setting, however, they are tied together, as they both emerge from the information spillover from the real to the financial sector.

Finally, note that there also exists an inefficiency in the level of startup decisions. That is, even if \(b^\diamond = b^\ast\), in general \(c^\diamond \neq c^\ast\). This is akin to the holdup problem. The private surplus from starting a project is \(\beta^2 (1 - \alpha) \Theta f(K)\), while the social surplus is \(\beta^2 \Theta f(K) - \beta K\). Under complete information, the two coincide, but with informational frictions, their expected values may differ.

### 5.2 Policy

What kind of policies could help improve the equilibrium use of information? We have identified two types of inefficiency: one regarding the entrepreneurs’ excessive concern about the market’s valuation of their projects; the other regarding the informational externality from initial investment, \(N\), to subsequent expansion, \(K\). Below, we show that both inefficiencies can be corrected by introducing a subsidy/tax to

---

\(^{16}\)Recall that, in equilibrium, the shares sold by entrepreneur \(i\) are \(s_i = \alpha\) and their price is \(p_i = \hat{\Theta} f(k)\), so that \(s_i \cdot \Theta f(k) = \alpha \Theta f(k)\), and \(p_i \cdot s_i = \alpha \hat{\Theta} f(k)\).
entry that is contingent on the realized asset price, even if this subsidy cannot be contingent on the realized fundamental.\footnote{One can think of this policy in two ways: (i) the subsidy is paid in stage 3, at which point both $p$ and $\Theta$ are publicly known, but is restricted to depend only on $p$; (ii) the subsidy is paid at the end of period 2 after the IPO is completed and the capital expansion $k$ is finalized, at which point $p$ is publicly known but $\Theta$ is still uncertain. In either case, in those states in which the subsidy takes on negative values (i.e., is a tax), for simplicity one can think of the entrepreneurs paying it by exerting effort, with the latter generating the consumption good at a 1-1 rate.}

Let us start with the first inefficiency, which is more central to our theory. To simplify the exposition, assume momentarily that $\beta = 1$. As explained above, this inefficiency boils down to a discrepancy between the private return to entry, given by $E_i[\Pi(\Theta, \hat{\Theta})] - 1$, and the social return to entry, given by $E_i[Q(\Theta, \hat{\Theta})] - 1$. Denote the aforementioned subsidy by $\sigma(p)$, with $p$ representing the average price in the market.\footnote{Conditioning the subsidy on the average IPO price instead of the \textit{firm-specific} price guarantees that the entrepreneur cannot manipulate the subsidy through her choice of a supply schedule.} Each entrepreneur’s net payoff from entry is then given by $E_i[\Pi(\Theta, \hat{\Theta}) + \sigma(p) - 1]$. Now suppose that the subsidy takes the form

$$\sigma(p) \equiv 1 - (1 - \alpha)(1 + \alpha p).$$

Recall that, in equilibrium,

$$K(\hat{\Theta}) = \alpha p \quad \text{and} \quad p = \hat{\Theta} f(K(\hat{\Theta})).$$

It follows that the subsidy satisfied $\sigma(p) = 1 - (1 - \alpha)(1 + K(\hat{\Theta}))$ and, by implication, the entrepreneur’s net payoff satisfies

\[
E_i[\Pi(\Theta, \hat{\Theta}) + \sigma(p) - 1] = E_i[(1 - \alpha)\Theta f(K(\hat{\Theta})) - (1 - \alpha)(1 + K(\hat{\Theta}))] \\
= (1 - \alpha)E_i[\Theta f(K(\hat{\Theta})) - K(\hat{\Theta}) - 1] \\
= (1 - \alpha)E_i[Q(\Theta, \hat{\Theta}) - 1].
\]

The above subsidy thus aligns the private return to entry to the social return.

To understand the nature of this subsidy, it is useful to rewrite it as

$$\sigma(p) = -b(p - p^\#$

where $b \equiv \alpha(1 - \alpha)$ and $p^\# \equiv 1/(1 - \alpha)$. By making the subsidy decrease with the realized price, the planner “penalizes” the entrepreneurs for conditioning their entry decisions too much on their expectations of asset prices and, thereby, tilt their relative use of information. At the same time, by choosing appropriately $p^\#$, or the intercept of the subsidy, the planner can regulate the level of entry. Together, these properties allow the planner to correct the inefficiency in the entry decisions caused by the speculative motive identified earlier.\footnote{The specific value of $p^\#$ given above may look mysterious at first, but it has a natural interpretation. Consider the full-information benchmark. Note that in this case the social (and also the private) return to entry satisfies $Q(\Theta, \theta) = \max_k(\Theta f(k) - k)$, which is strictly increasing in $\Theta$. Let $\theta^\#$ be the unique solution to $Q(\theta^\#, \theta^\#) = 1$, which means that $\theta^\#$ is the fundamental threshold above which entry is optimal under full information. Then, $p^\# = \theta^\# f(K(\theta^\#))$, which allows us to interpret $p^\#$ as the price threshold for entry under complete information. When $\Theta = \theta^\#$, and hence $p = p^\#$, the subsidy ought to be zero, or else it would distort entry under full information and, by extension, it would not be optimal under incomplete information either.}
So far, we have shown how to correct the main inefficiency of interest. What about the second inefficiency, that regarding the informational externality? Because a subsidy that declines with $p$ induces the entrepreneurs to rely more on their idiosyncratic sources of information (i.e., on $x_i$ relative to $y$), such a subsidy can also improve the aggregation of information via $N$. This suggests that the same type of policy can correct both inefficiencies. The next proposition verifies that this intuition is correct.

**Proposition 7.** The socially-optimal startup rule of Proposition 6 can be implemented as an equilibrium by giving to those entrepreneurs who started a project at $t = 1$ and completed their IPO at $t = 2$ a (possibly negative) subsidy equal to

$$
\sigma^*(p) = \frac{1}{\beta} \left( 1 - \exp \{ B \ln p - C \} \right)
$$

for some $B > 0$ and $C \in \mathbb{R}$.

The subsidy in Proposition 7 shares with the simpler one described above the latter’s key monotonicity: it is decreasing in $p$. However, it has a different functional form, to induce a Gaussian equilibrium (which we impose in Proposition 6 to characterize the informational externality and pin down the optimal linear startup rule). While the slope of the simple subsidy described above with respect to $p$ is pinned down by $\alpha$ alone, the slope of the subsidy in Proposition 7 also depends on the “details” of the information structure. This is because the latter details determine the extent of the informational externality. Notwithstanding these subtleties, the main take-home message is that a policy that “leans against the wind” can help improve the efficiency of the equilibrium decisions at all stages, and reduce the magnitude of noise-driven IPO waves.

Needless to say, the policy described above is not the unique way to “lean against the wind.” For instance, if one takes our model “as is,” it is possible to implement the socially-optimal entry rule by replacing the contingency on $p$ with one on $N$ in the subsidy described above or with a tax/subsidy in stage 3 that is contingent on $\Theta$. However, if we think of stage 3 as something sufficiently remote in the future, at which point the firm has matured but its original founders have possibly exited, the anticipation of a subsidy/tax levied at that point may have a a more limited, or even a muted, effect on entry decisions. For this reason, we find the “real-time” policy described above, as well as the policies described next, more appealing.

Consider now a tax on financial trades collected from the investors in period 2. Proposals for such taxes have received a lot of attention in recent years; here, we study their merits within the confounds of our analysis. When an investor buys $s$ shares, her total cost is $(1 + \tau)p_s$, where $\tau$ is the tax rate. By letting $\tau$ itself be a function of the average price $p$, the planner can influence how asset prices vary with $\hat{\Theta}$, the investors’ expectation of the fundamental, and, thereby, also influence the entrepreneurs’ entry decisions. In particular, the more steeply $\tau$ increases with $p$, the less $p$ itself varies with $\hat{\Theta}$ and, therefore, the less sensitive the entrepreneurs’ entry decisions to the “speculative” motives. In this respect, this policy achieves the same goal as the subsidy described above. However, such a policy comes at a cost: by dampening the response of $p$ to $\hat{\Theta}$, it distorts the investment at stage 2.\textsuperscript{20}

\textsuperscript{20}Indeed, whenever $\tau \neq 0$, we have that $p \neq \hat{\Theta}f(k)$ and, as a result, $K(\hat{\Theta}) \neq \arg\max_k (\hat{\Theta}f(k) - k)$.
between improving entry decisions and distorting firms’ subsequent expansions, and the “unrestricted” optimum of Proposition 6 is no longer attainable. Nonetheless, this policy shares with the one described above both the spirit of “leaning against the wind” and the function of improving entry decisions.

Next, consider a cap on the shares that the entrepreneurs can sell to the stock market, which is another policy that has received some attention in the policy debate. To see how such a policy can improve over the laissez-faire equilibrium, one needs to adjust the framework by making the realistic assumption that not all entrepreneurs get to do an IPO. In particular, let each entrepreneur have the opportunity to access the stock market and undertake the kind of expansion described above with probability \( \lambda \in (0, 1) \); with the complementary probability \( (1 - \lambda) \), the entrepreneur, instead, is excluded from the IPO market in which case the return to her project is given by \( q\Theta \), for some \( q > 0 \). Consider then a policy that constrains each entrepreneur to sell no more than \( \bar{s} \in (0, 1) \) shares, where \( \bar{s} \) is the cap on the sale of IPO shares. It is straightforward to check (i) that the cap is binding if and only if \( \bar{s} < \alpha \) and (ii) such a cap tilt the use of information in the direction of increasing the sensitivity of entry decisions to fundamentals. Intuitively, requiring the entrepreneurs to keep more “skin in the game” reduces the extent to which their decisions are driven by speculative motives and can therefore improve the efficiency of their entry decisions.

The common thread of all the policies described above is that they help ease the bite of speculative motives on entry decisions and IPO activity: entrepreneurs (and the venture capitalists behind) are induced to think more about fundamentals and less about (speculative) IPO returns. The analysis above provides a precise rationale for this kind of policy interventions.

### 6 Robustness and Enrichments

Our analysis identifies an informational mechanism that induces strategic complementarity in entrepreneurial decisions. It abstracts from the standard “neoclassical” mechanism that can contribute in the opposite direction: when the supply of capital in the financial market is imperfectly elastic (that is, when entrepreneurs “compete for limited funding”), more aggregate entry in stage 1 raises the expected cost of funding in stage 2, thus discouraging individual entry. In the first part of this section, we show how this traditional mechanism contributes to strategic substitutability, without however changing the essence of our mechanism or its normative/policy implications: entry and IPO waves remain over-responsive to “noise.” In the second part, we then discuss a few possible re-interpretations of such “noise” and additional dimensions of robustness.

#### 6.1 Information complementarity meets neoclassical substitutability

To accommodate for the aforementioned neoclassical channel, it suffices to introduce convexity in the investors’ opportunity cost of investing in IPOs. We do so by letting investors consume only in the last period and modifying their preferences as follows

\[
V = -\frac{1}{1+\epsilon}l^{1+\epsilon} + u\left(u^{-1}(E_2[u(c_3)])\right),
\]
where \( u(c) \equiv \frac{c^{1-\gamma}}{1-\gamma}, \ v(x) \equiv \frac{x^{1-\sigma}}{1-\sigma}, \ \varepsilon, \gamma, \sigma \geq 0, \) and where \( \mathbb{E}_2[\cdot] \) is a shortcut for the investors’ expectation given their period-2 information. The benchmark model is nested as \( \varepsilon = \gamma = \sigma = 0. \) Relative to that benchmark, the above representation allows for risk aversion (\( \gamma > 0 \)), imperfect intertemporal substitutability (\( \sigma > 0 \)), and a convex disutility of labor (\( \varepsilon > 0 \)). For simplicity, and without any loss of generality, we also let \( \beta = 1. \) Let

\[
\tilde{\Theta} \equiv u^{-1}(\mathbb{E}_2[u(\Theta)]) = \hat{\Theta} \cdot \exp\left\{ -\frac{\gamma}{2} \text{Var} (\theta | \mathcal{I}) \right\}
\]
denote the investor’s risk-adjusted expectation of \( \Theta. \) The next lemma explains how these enrichments affect the equilibrium amount of funds raised, and invested, in stage 2.

**Lemma 2.** The equilibrium investment in stage 2 is given by \( k_i = k \) for all \( i, \) where \( k \) solves the following condition:

\[
a \tilde{\Theta} k^{a-1} = (\alpha N \tilde{\Theta} k^a) \sigma (N)^{\varepsilon}.
\]

(29)

The left-hand side of (29) captures the marginal product of capital, whereas the right-hand side captures the marginal cost of investment (or the marginal cost of funding). When \( \varepsilon = \gamma = \sigma = 0, \) this condition reduces to

\[
a \tilde{\Theta} k^{a-1} = 1,
\]

which is the counterpart of the optimality condition in the benchmark model. Note that the benchmark model embeds two key properties: the investor’s risk-neutral expectation of \( \Theta, \) and the fact that the marginal cost of investment is fixed at 1. Relative to this benchmark, letting \( \gamma > 0 \) replaces the risk-neutral expectation \( \hat{\Theta} \) with the risk-adjusted expectation \( \tilde{\Theta}, \) but does not affect the second property. By contrast, letting \( \varepsilon > 0 \) and/or \( \sigma > 0 \) breaks the second property: the marginal cost of investment becomes an increasing function of both \( k \) and \( N. \) This is because a higher total investment in stage 2 raises the investor’s cost of generating funds (“the cost of working”) whenever \( \varepsilon > 0, \) and a higher income in stage 3 reduces the investor’s marginal utility of dividends whenever \( \sigma > 0. \)

The next proposition summarizes how these enrichments affect entry decisions and the associated game among the entrepreneurs.

**Proposition 8.** In equilibrium, each entrepreneur starts a project if and only if

\[
\mathbb{E}_i \left[ \exp \left\{ \frac{1+\varepsilon}{1-a(1-\sigma)+\varepsilon} \left[ (1-\varphi)\theta + \varphi \tilde{\Theta} - \psi \log N \right] \right\} \right] \geq \tilde{c},
\]

(30)

where \( \tilde{c} \) is a constant, \( \tilde{\Theta} = \log \tilde{\Theta}, \)

\[
\varphi \equiv \alpha \frac{1-\sigma}{1+\varepsilon} \quad \text{and} \quad \psi \equiv \alpha \frac{\sigma + \varepsilon}{1+\varepsilon}.
\]

When \( \varepsilon = \gamma = \sigma = 0, \) condition (30) reduces to

\[
\mathbb{E}_i \left[ \exp \left\{ \frac{1}{1-a} \left[ (1-\alpha)\theta + a\tilde{\Theta} \right] \right\} \right] \geq c,
\]

(31)
which is de facto the same condition as (14) in the baseline model. Relative to the benchmark, there are three changes. First, \( \hat{\theta} \) is replaced by \( \tilde{\theta} \). This allows entry to respond to “risk shocks” in the financial market.

Second, \( \alpha \) is replaced with \( \varphi \), where \( \varphi \) is necessarily lower than \( \alpha \). This shows how, holding \( \alpha \) constant, our informational mechanism is attenuated by the neoclassical mechanism: a higher \( \tilde{\theta} \) now has a subdued effect on the supply of funds in stage 2. In fact, it is conceivable that a higher \( \tilde{\theta} \) even reduces investment in stage 2, but this is possible only when the negative wealth effect on saving overwhelms the positive substitution effect (herein captured by \( \sigma > 1 \)), which seems improbable in practice, especially if we take into account that in reality the investment returns we study here are likely to be only a fraction of the investor’s consumption.

Finally, and most importantly for the present purposes, the entry rule now contains the additional term \(-\psi \log N\). This is the effect anticipated at the beginning of the section: the “neoclassical” source of strategic substitutability.

Clearly, whether entrepreneurial decisions are, overall, strategic complements or substitutes depends on how strong our novel, informational mechanism is relative to the familiar, neoclassical mechanism. To the extent that our model applies to a specific sector, rather than the entire economy, we expect the supply of funds to be quite elastic and, therefore, the neoclassical mechanism to be relative weak. At the same time, we expect our informational mechanism to be strongest in sectors involving new technologies.

Regardless of which mechanism prevails, it is only our mechanism that induces a wedge between the private and social incentives: unlike ours, the neoclassical mechanism is not, on its own right, a source of inefficiency. This should not surprise, because this mechanism is merely the analogue of the kind of “innocuous” pecuniary, or GE, externalities that populate the Arrow-Debreu paradigm but do not on their own right upset the welfare theorems. Finally, the incorporation of risk aversion seems only to reinforce our normative conclusions: as the risk premium demanded by the investors, and the associated cost of expansion, decreases with the precision of information contained in \( N \), there is yet another reason for the planner to induce the entrepreneurs to base their entry decisions more heavily on fundamentals.

---

21 In this enriched model, the equilibrium is not guaranteed to be Gaussian, which explains why the entry rule in the proposition is not expressed as a linear combination of the relevant variables, as in condition (14) in the benchmark model.

22 This fact can be readily verified when \( \sigma = 0 \), which still allows \( \psi > 0 \) insofar as \( \epsilon > 0 \). Things are a bit more subtle when \( \sigma > 0 \), because this raises the possibility that the planner may wish to manipulate market outcomes in an attempt to redistribute income from entrepreneurs to investors or vice versa. This possibility seems orthogonal to the question of interest; it could have been raised even in our main analysis by introducing a concave welfare aggregator of the utilities of the two groups of agents; and it can be avoided here either by restricting \( \sigma = 0 \) or by allowing for \( \sigma > 0 \) but specifying the welfare objective in a way that makes such redistribution undesirable.
6.2 Reinterpretations and additional robustness

We now discuss a few reinterpretations of our mechanism and its likely robustness to richer specifications of the IPO stage.\textsuperscript{23}

Noise. By assuming that all agents are rational and by abstracting from the possibility of sunspot fluctuations, we have imposed that all the non-fundamental variation in investment and asset prices is the product of correlated noise in dispersed private information. This has made clear that our amplification mechanism and its normative implications do not depend on a departure from rational expectations. Nevertheless, our insights are relevant more broadly. In particular, the non-fundamental waves in beliefs, investment, and asset prices we have documented here can readily be recast as the product of “irrational exuberance” by replacing the correlated error in the entrepreneurs’ information either with a correlated bias or a correlated taste for starting up a firm. Provided that investors cannot tell apart these drivers of entrepreneurial activity from fundamentals, our mechanism amplifies the noise.

Investor sentiment. We have interpreted $\omega$ as the investors’ unbiased signal about $\theta$ and have precluded the entrepreneurs from having any information about $\omega$ other than the one contained in their information about $\theta$. Suppose, instead, that $\omega$ represents a biased signal and that entrepreneurs receive a correlated private signal about $\omega$ or, equivalently, about the error in $\omega$. Denote this signal by $z^\omega \equiv \omega + u^\omega$, where $u^\omega$ is a new noise term. Naturally, a positive realization for $u^\omega$ triggers an increase in startup activity, because it makes entrepreneurs expect more optimism in asset markets. Perhaps more interestingly, because $z^\omega$ is not directly observed by the investors, the increase in startup activity will appear in their eyes as positive news for profitability. Our mechanism is thus switched on again, causing this kind of noise, too, to be amplified.

Elastic supply of shares. A key, simplifying property of our model is that, in the IPO stage, the entrepreneurs find it optimal to sell a constant fraction, $\alpha$, of their project to the asset market, regardless of their beliefs about $\theta$. This follows from the assumption that the entrepreneurs have no other way to finance the second-stage investment, $k$, and implies that there is no revelation of information in the IPO market. Suppose now that the entrepreneurs have access to some private funding, which is less attractive than an IPO on average but also less sensitive to investors’ beliefs. For example, suppose that the entrepreneurs can work in stage 2 and use the proceeds of their work, in addition to the funds collected by selling shares, to finance $k$. Then, the entrepreneurs will find it optimal to work less and sell more shares when they think that IPOs are overvalued, which means that the supply of shares could itself reveal some of the entrepreneurs’ private information to the investors. An interesting question, left for future work, is whether in such situations there exist pooling equilibria that prevent any such revelation. But even if this is not the case, our mechanism remains active as long as such revelation of information remains imperfect.\textsuperscript{24}

Decoupling IPOs from startups. Our model has equated the number of IPOs with the number of start-
tups, $N$. The most trivial way to decouple the two is to let an exogenous random fraction of entrepreneurs get access to the IPO market. More interestingly, one could endogenize the IPO margin along similar lines as those described above: like the decision of how many shares to sell, the decision to do any IPO in the first place could be sensitive to entrepreneurs' private information, implying that IPO volume could contain additional information over startup activity. But as long as IPO volume does not perfectly reveal $y$ to the investors, our mechanism remains active. What is more, if the private return to an IPO inherits the monotonicity properties of the private return to a startup (i.e., it increases with the expectations of both $\theta$ and $p$), our mechanism is bound to give rise to strategic complementarily not only at the startup margin but also at the IPO margin. This helps bring our theory even closer to the facts about IPO waves we discuss in the next section.

**Richer dynamics.** So far we have assumed that all startups take place simultaneously in stage 1, and similarly that all IPOs take place simultaneously in stage 2. Suppose, instead, that each stage has two phases, an early one and a late one, and that entrepreneurs are randomly selected to be "early movers" or "late movers" in both stages. Late movers may naturally have an informational advantage, but this does not change the essence of our message. To illustrate, consider the most extreme scenario in which early and late movers receive the same correlated signal $y$, but late movers also get to see the startup activity of the early movers. Then, late movers will learn perfectly $\theta$ and will face no uncertainty about $N$ and its subcomponents. But as long as the investors get to see either a possibly perfect signal of $N$ or two noisy signals of the early and late startup activities, neither $y$ nor $\theta$ will be perfectly revealed to them. As a result, all entrepreneurs—both the early ones and the late ones—will be able to forecast the asset market mis-pricing when making their startup decisions, as in our baseline model.

Also note that, under the assumptions made thus far, there is no revelation of information between the early and the late IPO phases. This is because both the selection of who goes first and the number of shares sold is independent of the entrepreneurs' private information. One could of course relax these assumptions, but for the reasons already explained above we do not expect this to overturn the message.

These points clarify that our results do not rely on the following two simplifying assumptions: that all startup decisions take place with symmetric information; and that entrepreneurs face uncertainty about each others’ decisions. Instead, our results are driven by the following two key properties: that a larger startup/IPO activity is interpreted by financial markets as a positive signal about profitability; and that entrepreneurs naturally have some private information relative to financial markets (but not necessarily relative to one another) about the drivers of their startup decisions. We expect these properties to extend to models that tackle more seriously the dynamics of both startup and IPO activity.25

25See also Alti (2005) for information spillovers from early IPOs to later ones.

26See, among others, Hellwig and Veldkamp (2009), Myatt and Wallace (2012), Colombo, Femminis and Pavan (2014), Chahrour
crease the entrepreneurs’ incentives not only to react to sources of information with correlated noise, but also to collect such information in the first place—e.g., to rely on common consultants, participate in the same conferences, business fairs, social events, etc. This hints at possible empirical proxies for the “noise” in our model, a point we return to in the next section.

7 Discussion and Conclusions

Our paper offers a new perspective on the interaction between real investment and asset markets, focusing on periods of fast technological change and intense startup activity. Because higher startup activity may signal stronger fundamentals (higher eventual profitability), external investors’ willingness to provide funds to any given startup may increase with aggregate startup activity, inducing a strategic complementarity, or a “beauty contest,” in startup activity and IPO entry. This mechanism amplifies the non-fundamental waves in real investment, IPO volume, and IPO prices. It also creates a wedge between private and social incentives, offering in turn a rationale for policies of “leaning against the wind.”

As mentioned in the Introduction, this mechanism seems broadly consistent with the phenomena studied in the literature on IPO waves and hot IPO effects. In the rest of this section, we expand on this connection and discuss possible new venues for empirical work.

The aforementioned literature has documented that IPOs tend to be clustered in time, both at the aggregate and the sectoral level, as indicated in Figure 1 in the Introduction. The interpretation of this clustering through the lens of our model is that a high volume of startup activity and IPOs in a given sector sends a positive signal to the financial market about the sector’s profitability. Such a signal boosts IPO prices and induces more startup activity and more IPOs, thus reinforcing the wave. In our model, the decision to go public follows mechanically that of starting a firm and there is no decision of “when” to go public. However, the endogenous complementarity uncovered by our mechanism appears broadly consistent with the empirical evidence that aggregate market conditions matter for the decision to go public and that IPO prices tend to be positively correlated with various measures of startup activity and IPO volume (see Loughran et al., 1994 for an early paper showing that IPO volume tends to be higher when the level of the stock market is higher).

This finding is subject to many interpretations as a high stock market value could reflect high expected returns for the entrepreneurs thus reflecting an increase in investment opportunities and in the demand for capital, rather than the entrepreneurs’ response to outside investors’ supply of funds. For this reason, the empirical literature has tried to identify variations in stock valuations that are more likely to be driven purely by investors’ optimism. Pagano, Panetta and Zingales (1998) show that companies are more likely to go public when the market-to-book ratios of public companies in the same industry are high. Lowry (2003) uses various proxies for investor sentiment, in particular the discount on closed-end funds and post-IPO market returns, and concludes that “firms seem to successfully go public when a broad class of firms, often the entire market, is valued especially highly.”

In our model, firms go public to raise funds to invest in the firm. This also seems consistent with what documented in the IPO literature. For example, the same study by Lowry (2003) shows that IPO volume is higher when firms’ demands for capital (as proxied by changes in output or investment) is higher.

A large part of the empirical IPO literature focuses on the long-run underperformance of IPOs (Ritter, 1991) and on behavioral interpretations of such a phenomenon (Shiller, 1990, Lee, Shleifer, and Thaler, 1991). As anticipated in the Introduction, Pastor and Veronesi (2005) has criticized this literature for assuming that investors cannot detect mis-pricing that entrepreneurs can detect, and has provided an alternative explanation of the clustering of IPOs based on time-varying risk premia. In our model, the entrepreneurs’ advantage vis-a-vis the investors stems from the fact that part of the latter’s overoptimism originates in the observation of the former’s activity thus providing the entrepreneurs with an informational advantage when it comes to interpreting the drivers of such optimism. Our theory thus hinges on the presence of frictions that limit the capacity of prices to fully aggregate all available information, but does not require one to take a stand on investors’ rationality.

So far we have discussed how our theory is broadly consistent with existing evidence. But how could one test more directly for our mechanism? And does our theory suggest new empirical explorations?

First, one could test for conditional mis-pricing. Our model predicts that, when controlling for fundamentals, a higher level of aggregate startup activity leads to more underperformance following the IPO. Indeed, in our model, the return $\Theta f(k) - P$ on IPO stocks is negatively correlated with aggregate startup activity $N$, when controlling for fundamentals $\Theta$. To test this prediction one could use the same measures of stock overvaluation used in the IPO literature (e.g., post-IPO market returns) at the sectoral level and look at their correlation with pre-IPO startup activity, the aggregate volume of IPOs in the same time window, and real investment in the same sector. The two main challenges with such an approach are the following: (i) first, one needs to find reasonable proxies for the “fundamental” value of firms’ stocks $\Theta f(k)$;\(^{27}\) (ii) second, one needs measures of pre-IPO startup activity and investment that are comparable across different sectors and that can be used to build a sample that includes sectors that did not experience significant IPO activity, to get around obvious selection issues. In this respect, it is worth highlighting an important difference between this approach and the one in the literature on hot IPO issues and their long-term underperformance. That literature focuses on unconditional mis-pricing. It documents a negative relation between the volume of IPOs and the return to IPO stocks after a certain number of years. Without conditioning on proxies for $\Theta$, our theory predicts no underperformance and zero correlation between aggregate startup activity (or IPO volume) and the long-term return on IPO stocks.

It would also be interesting to test empirically for some of the comparative statics that the model delivers. Our mechanism is likely to be more relevant in sectors where (i) firms rely intensively on external funding (in the model, this is captured by a high level of the parameter $\alpha$), (ii) there is more uncertainty about the profitability of new technologies (higher $\sigma^2_\theta$) and (iii) entrepreneurs are exposed to more correlated noise (larger $\sigma^2_\epsilon$). Provided that one can identify appropriate measures of long-term fundamental

\(^{27}\)One could perhaps follow the prevalent approach in the literature on underperformance and look at post-IPO market returns over some fixed horizon, taking the value of the firm at longer horizons after the IPO as a proxy for its fundamental value.
profitability to address the issue of conditional underperformance discussed above, it would be interesting to study how the correlation between long-term underperformance and IPO volume (or early startup activity as proxied by venture-capital investment) varies across industries and time. As mentioned above, the evidence in Jain and Kini (2006) that IPO clustering tends to occur prevalently in fragmented, high growth, R&D-intensive industries seems to provide some support to the comparative statics of our mechanism but more work in this direction is needed. The main challenge here, in addition to those discussed above, is in finding reasonable proxies for the degree to which investors rely on IPO finance (α) and for their exposure to correlated noise. The latter could be captured in part by the extent to which entrepreneurs in a given sector rely on common venture capitalists and common consultants, or, alternatively, by their network connections (e.g., the schools they attended, and the participation to similar industry events such as fairs, forums, and other venues for business networking).

We conclude with the following observation. While we focused on IPO waves and the associated “hot IPO effect” as a natural context for our theory, we expect our mechanism to extend to the broader real-financial nexus and to find an application at the business-cycle level, too. This would bring our theory closer to the literature, also mentioned in the Introduction, that documents the response of asset prices to news about real economic activity (Chen, Roll and Ross, 1986; Cutler, Poterba, and Summers, 1989). As usual, the higher the level of aggregation, the lesser the hope for clean identification. This suggests that the empirical exercises mentioned above may prove useful, not only in the IPO context, but also for a micro-to-macro application of our theory at the business-cycle level.

Appendix: Proofs

Proof of Proposition 1. In this proof we fill in the details of the equilibrium characterization in Section 3 and provide explicit expressions for the functions Γ and Λ.

First, let us derive the optimality condition (14), which we rewrite here for convenience:

$$E_i[(1 - \alpha)\theta + \alpha\hat{\theta}] \geq C,$$  

and provide an explicit expression for the constant $C$. In the text we argued that an entrepreneur will start up the project if and only if

$$\beta^2(1 - \alpha)(\alpha\beta)^1 = E_i[\Theta \cdot \hat{\Theta}^{\alpha\beta}] \geq 1.$$  

As argued in the text, conditional on the investors’ information $\mathcal{I}$, $\theta$ is normally distributed with mean

$$\hat{\theta} = \frac{\pi z}{\pi} \omega + \frac{\pi z}{\pi} z$$  

(which corresponds to (18) in the text) and variance $\pi^{-1}$, so we can compute

$$\hat{\Theta} = E[e^{\hat{\theta}}|\mathcal{I}] = \exp \left\{ \hat{\theta} + \frac{1}{2} \pi^{-1} \right\}.$$
We can then compute the expression $E_i[\Theta \cdot \hat{\Theta}]$ in (33) as follows

$$
E_i[\Theta \cdot \hat{\Theta}] = E_i \left\{ \exp \left\{ \frac{(1 - \alpha) \theta + a\hat{\theta}}{1 - \alpha} + \frac{\alpha}{1 - \alpha} \frac{1}{2\pi} \right\} \right\} = 
$$

$$
\exp \left\{ E_i \left\{ \frac{(1 - \alpha) \theta + a\hat{\theta}}{1 - \alpha} + \frac{\alpha}{1 - \alpha} \frac{1}{2\pi} \right\} + \frac{1}{2} V a r_i \left\{ \frac{(1 - \alpha) \theta + a\hat{\theta}}{1 - \alpha} \right\} \right\}.
$$

Substituting into (33), we obtain condition (32), where

$$
C = -(1 - \alpha) \ln \left( \beta^2 (1 - \alpha)(\alpha \beta) \frac{\alpha}{\pi} \right) - \frac{\alpha}{2} \pi^{-1} - \frac{1}{2(1 - \alpha)} V a r_i \left\{ (1 - \alpha) \theta + a\hat{\theta} \right\}.
$$

Joint normality of $(1 - \alpha) \theta + a\hat{\theta}$ and of the signals $(x_i, y)$ imply that the conditional variance in the last term is a constant independent of the realization of $(x_i, y)$.

Next, let us solve the Bayesian updating problem of entrepreneurs at the startup stage. Substituting $z = (1 - b) \theta + by$ (which corresponds to (17) in the text) in (34) we have

$$
\hat{\theta} = \frac{\pi \omega}{\pi} \left( \theta + \eta \right) + \frac{\pi z}{\pi} \left( (1 - b) \theta + by \right),
$$

so

$$
(1 - \alpha) \theta + a\hat{\theta} = \left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right) \theta + \alpha \frac{\pi z}{\pi} by + \alpha \frac{\pi \omega}{\pi} \eta.
$$

Conditional on $(x_i, y)$, the posterior distribution of $\theta$ has mean

$$
E_i[\theta] = \delta_x x_i + \delta_y y,
$$

with

$$
\delta_x = \frac{\pi x}{\pi \omega + \pi x + \pi y}, \quad \delta_y = \frac{\pi y}{\pi \omega + \pi x + \pi y},
$$

and variance $(\pi \omega + \pi x + \pi y)^{-1}$. Moreover $(x_i, y)$ contains perfect information on $y$ and no information on $\eta$. Therefore, the posterior mean and variance of $(1 - \alpha) \theta + a\hat{\theta}$ are

$$
E_i[(1 - \alpha) \theta + a\hat{\theta}] = \left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right) \left( \delta_x x_i + \delta_y y \right) + \alpha \frac{\pi z}{\pi} by,
$$

$$
V a r_i[(1 - \alpha) \theta + a\hat{\theta}] = \left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right)^2 \frac{1}{\pi \omega + \pi x + \pi y} + \left( \alpha \frac{\pi \omega}{\pi} \right)^2 \frac{1}{\pi \omega}.
$$

We can now go back to the optimality condition (32), substitute (37) and obtain

$$
\left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right) \left( \delta_x x_i + \delta_y y \right) + \alpha \frac{\pi z}{\pi} by \geq C.
$$

Matching the coefficients of this condition to the coefficients of the entrepreneur's strategy (15), we obtain

$$
b = \frac{\left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right) \delta_y + \alpha \frac{\pi z}{\pi} b}{\left( 1 - \alpha + \frac{\alpha \pi \omega + \pi z (1 - b)}{\pi} \right) \left( \delta_x + \delta_y \right) + \alpha \frac{\pi z}{\pi} b},
$$

(39)
and
\[
c = \frac{C}{\left(1 - \alpha + \alpha \frac{\pi_x + \pi_z (1 - b)}{\pi}\right) (\delta_x + \delta_y) + \alpha \frac{\pi_x b}{\pi}}.
\]  
(40)

Substituting \(\pi = \pi_\theta + \pi_\omega + \pi_z\) and \(\pi_z = \pi_y / b^2\) we can rewrite the right-hand side of (39) as
\[
\frac{\left(1 - \alpha\right) \left(\pi_\theta + \pi_\omega + \frac{\pi_z}{\pi}\right) + \alpha \left(\pi_\omega + \frac{\pi_z}{\pi} (1 - b)\right)}{\left(1 - \alpha\right) \left(\pi_\theta + \pi_\omega + \frac{\pi_z}{\pi}\right) + \alpha \left(\pi_\omega + \frac{\pi_z}{\pi} (1 - b)\right)} (\delta_x + \delta_y) + \alpha \frac{\pi_x b}{\pi},
\]
which can be rearranged to yield
\[
\Gamma (b) \equiv \frac{\left(\left(1 - \alpha\right) \pi_\theta + \pi_\omega\right) b^2 + \pi_y - \alpha \pi_y b - \alpha \pi_y b}{\left(\left(1 - \alpha\right) \pi_\theta + \pi_\omega\right) b^2 + \pi_y - \alpha \pi_y b} (\delta_x + \delta_y) + \alpha \pi_y b.
\]  
(41)

This shows that the equilibrium value of \(b\) can be found finding a fixed point of the function \(\Gamma\), which only involves known parameters of the model.

The mapping \(\Lambda (b)\) is given by the right-hand side of (40), after substituting \(C\) from (36), substituting \(\text{Var}_f \left[(1 - \alpha) \theta + a \hat{\theta}\right]\) from (38), and finally substituting \(\pi = \pi_\theta + \pi_\omega + \pi_z\) and \(\pi_z = \pi_y / b^2\), so as to obtain an expression that only involves known parameters and \(b\). This shows that the equilibrium value of \(c\) can be computed by simple algebra after having found a \(b\) that solves \(b = \Gamma (b)\). Q.E.D.

**Proof of Proposition 2.** Part (i): Existence. First, notice that \(\Gamma (1) < 1\) so there is no equilibrium with \(b = 1\). Now define \(B = b / (1 - b)\) for any \(b \neq 1\). Using the definition of \(\Gamma\) we then have that \(b = B / (1 + B)\), corresponds to an equilibrium if and only if
\[
B \equiv \frac{b}{1 - b} = \frac{\Gamma (b)}{1 - \Gamma (b)} = \frac{\alpha \pi_y b + \left[\left(1 - \alpha\right) b^2 \pi_\theta + b^2 \pi_\omega + \pi_y - \alpha \pi_y b\right] \delta_y}{\left[\left(1 - \alpha\right) b^2 \pi_\theta + b^2 \pi_\omega + \pi_y - \alpha \pi_y b\right] \delta_x}.
\]

Letting
\[
F (B) \equiv \frac{\delta_y}{\delta_x} \left(1 + \frac{\alpha (1 + B) B}{\left[\left(1 - \alpha\right) \left(1 - \delta_x\right) + \Omega \right] B^2 + (2 - \alpha) \delta_y B + \delta_y}\right),
\]  
(42)

with \(\Omega \equiv \frac{\pi_x + \pi_y}{\pi_x + \pi_y + \pi_\theta} > 0\), and noting that \(B\) is a one-to-one transformation of \(b\), we then have that the solutions to the equations \(B = F (B)\) identify the solutions to the equation \(b = \Gamma (b)\) and vice versa.

It is easy to see that \(F\) is well defined and continuous over \(\mathbb{R}_+\), with \(F \left(\delta_y / \delta_x\right) > \delta_y / \delta_x\) and \(\lim_{B \to +\infty} F (B)\) finite. It follows that \(F\) has at least one fixed point \(B > \delta_y / \delta_x\). Given this value of \(B\), existence of an equilibrium then follows by letting \(b = B / (1 + B)\). That \(B > \delta_y / \delta_x\) in turn implies that
\[
b > \frac{\delta_y}{\delta_x + \delta_y} = \frac{\pi_y}{\pi_x + \pi_y} \equiv \delta.
\]
That \(B > 0\) in turn implies that \(b < 1\). We conclude that a solution \(b \in (\delta, 1)\) to \(\Gamma (b) = b\) always exists, as claimed in the proposition. The implications for \(N, P,\) and \(\hat{\theta}\) follow directly from the arguments in the main text.
Part (ii): Uniqueness. To prove uniqueness, note that all equilibria must correspond to a fixed point of the mapping \( F \) defined in (42). Next, note there exists \( \alpha' > 0 \) such that, for any \( \alpha \in [0, \alpha'] \) the denominator in the fraction in the right-hand side of (42) is strictly positive, for any \( B \in \mathbb{R} \). This implies that, when \( \alpha \in [0, \alpha'] \), the function \( F \) is defined and continuously differentiable over the entire real line, with

\[
F' (B) = \frac{\delta_y \left[(1 - \alpha)(1 - \delta_x - \delta_y) + \Omega\right] B^2 + 2 \delta_y B + \delta_y}{\delta_x \left[((1 - \alpha)(1 - \delta_x) + \Omega)B^2 + (2 - \alpha)\delta_y B + \delta_y\right]^2}
\]

Moreover,

\[
\lim_{B \to -\infty} F(B) = \lim_{B \to +\infty} F(B) = F(\infty) = \frac{\delta_y}{\delta_x} \left[1 + \frac{\alpha}{(1 - \alpha)(1 - \delta_x) + \Omega}\right] > \frac{\delta_y}{\delta_x}.
\]

Thus, from now on, restrict attention to \( \alpha < \alpha' \). We now need to consider two cases. First, suppose \( \delta_y = (1 - \alpha)(1 - \delta_x) + \Omega \). The function \( F \) then has a global minimum at \( B = -1/2 \). In this case, \( F \) is bounded from below and above, respectively, by \( F \equiv F(-1/2) \) and \( F \equiv F(\infty) \). Second, suppose \( \delta_y \neq (1 - \alpha)(1 - \delta_x) + \Omega \). Then \( F' (B) \) has two zeros, respectively at \( B = B_1 \) and at \( B = B_2 \), where

\[
B_1 \equiv \frac{-\delta_y - \sqrt{[(1 - \alpha)(1 - \delta_x - \delta_y) + \Omega] \delta_y}}{\delta_y - (1 - \alpha)(1 - \delta_x - \delta_y) - \Omega} \quad \text{and} \quad B_2 \equiv \frac{-\delta_y + \sqrt{[(1 - \alpha)(1 - \delta_x - \delta_y) + \Omega] \delta_y}}{\delta_y - (1 - \alpha)(1 - \delta_x - \delta_y) - \Omega}.
\]

When \( \delta_y \neq (1 - \alpha)\delta_0 + \Omega \), the function \( F \) then has a global minimum at \( F \equiv F(B_2) \) and a global maximum at \( F \equiv F(B_1) \). It is easy to check that in all the cases considered both \( F \) and \( F \) converge to \( \delta_y/\delta_x \) as \( \alpha \to 0 \). But then \( F \) converges uniformly to \( \delta_y/\delta_x \) as \( \alpha \to 0 \). It follows that for any \( \varepsilon > 0 \), there exists \( \tilde{\alpha} \leq \alpha' \) so that, whenever \( \alpha < \tilde{\alpha} \), \( F \) has no fixed point outside the interval \( [\delta_y/\delta_x - \varepsilon, \delta_y/\delta_x + \varepsilon] \).

Now, with a slight abuse of notation, replace \( F(B) \) with \( F(B;\alpha) \), to highlight the dependence of \( F \) on \( \alpha \). Notice that \( \partial F(B;\alpha)/\partial B \) is continuous in \( B \) at \( (B;\alpha) = (\delta_y/\delta_x, 0) \) and \( \partial F(\delta_y/\delta_x;0)/\partial B = 0 \). It follows that there exist \( \tilde{\varepsilon} > 0 \) and \( \tilde{\alpha} \in (0, \tilde{\alpha}] \) such that \( \partial F(B;\alpha)/\partial B < 1 \) for all \( B \in [\delta_y/\delta_x - \tilde{\varepsilon}, \delta_y/\delta_x + \tilde{\varepsilon}] \) and \( \alpha \in [0, \tilde{\alpha}] \). Combining these results with the continuity of \( F(B;\alpha)/\partial B \), we have that there exist \( \tilde{\varepsilon} > 0 \) and \( \tilde{\alpha} > 0 \) such that, for all \( \alpha \in [0, \tilde{\alpha}] \), the following are true: for any \( B \in [\delta_y/\delta_x - \tilde{\varepsilon}, \delta_y/\delta_x + \tilde{\varepsilon}] \), \( F(B;\alpha) \neq B \); for \( B \in [\delta_y/\delta_x - \tilde{\varepsilon}, \delta_y/\delta_x + \tilde{\varepsilon}] \), \( F \) is continuous and differentiable in \( B \), with \( \partial F(B;\alpha)/\partial B < 1 \). It follows that, if \( \alpha \leq \tilde{\alpha} \), \( F \) has at most one fixed point, which establishes the result.

Part (iii): Multiplicity. Consider the function \( F(B;\alpha, \delta_x, \delta_y, \Omega) \) introduced in the proof of part (ii). For convenience we are highlighting here the dependence on all parameters, with \( \Omega \equiv \frac{\pi a}{\pi x + \pi y + \pi \theta} \). Take the parameters \( (\alpha, \delta_x, \delta_y, \Omega) = (.75, .2, .1, .1) \). With these parameters the function \( F \) is defined and continuous over the entire real line and \( B_2 < B_1 \), where \( B_1 \) and \( B_2 \) are as defined in the proof of part (ii). Moreover, at the point \( B_2 \), we have that \( F(B_2;\alpha, \delta_x, \delta_y, \Omega) < B_2 < 0 \). These properties, together with the properties that \( F(0;\alpha, \delta_x, \delta_y, \Omega) > 0 \) and \( \lim_{B \to -\infty} F(B;\alpha, \delta_x, \delta_y, \Omega) > 0 \), ensure that, in addition to a fixed point in \( (\delta_y/\delta_x, +\infty) \), \( F \) admits at least one fixed point in \( (-\infty, B_2) \) and one in \( (B_2, 0) \). Furthermore, each of these three fixed point is "strict" in the sense that \( F(B) - B \) changes sign around them. Because \( F \) is continuous in \( (B;\alpha, \delta_x, \delta_y, \Omega) \) in an open neighborhood of \( (\alpha, \delta_x, \delta_y, \Omega) = (.75, .2, .1, .1) \), there necessarily exists an open set \( D \subset (0,1)^3 \times \mathbb{R} \) such that \( F \) admits at least three fixed points whenever \( (\alpha, \delta_x, \delta_y, \Omega) \in D \). The
result then follows by noting that for any \((\alpha, \delta, \delta', \Omega) \in D\), there corresponds a unique set of parameters \((\alpha, \pi, \theta, \pi, \pi_\omega) \in \mathbb{R}^5\). Q.E.D.

**Proof of Lemma 1.** The result is proved in the proof of part (i) of Proposition 2. Q.E.D.

**Proof of Proposition 4.** Using

\[
N = \Phi \left( \frac{\pi_x}{1-b^*} \left[ (1 - b^*) \theta + b^* y - c^* \right] \right)
\]

we have that the endogenous signal \(z\) can be written as

\[
z = \frac{1 - b^*}{\sqrt{\pi_x}} \Phi^{-1}(N) + c^*
\]

The investors’ forecast of the fundamentals can then be expressed as follows

\[
\hat{\theta} = \frac{\pi_x}{\pi_\theta + \pi_x} \omega + \frac{\pi_\omega}{\pi_\theta + \pi_x} \left( \frac{1 - b^*}{\sqrt{\pi_x}} \Phi^{-1}(N) + c^* \right)
\]

with \(\pi_x = \pi_y/(b^*)^2\). Replacing (43) into (14), we have that the entrepreneurs’ optimality condition can be written as

\[
n_i = 1 \iff \mathbb{E}_i \left[ (1-r) \theta + r \Phi^{-1}(N) \right] \geq c^#
\]

where

\[
r \equiv \frac{\alpha \pi_y (1-b^*)}{\alpha \pi_y (1-b^*) + [(1-\alpha) (\pi_\theta (b^*)^2 + \pi_y) + (b^*)^2 \pi_\omega] \sqrt{\pi_x}}
\]

and

\[
c^# \equiv \frac{[(\pi_\theta + \pi_\omega) (b^*)^2 + \pi_y] C - \alpha \pi_y c^*}{\frac{\alpha \pi_y (1-b^*)}{\sqrt{\pi_x}} + (1-\alpha) (\pi_\theta (b^*)^2 + \pi_y) + \pi_\omega (b^*)^2}
\]

with \(C\) as defined in (36). From (44) we then have that \(r > 0\) whenever \(b < 1\), i.e., whenever \(N\) is increasing in \(\theta\), which is always the case when the equilibrium is unique, for in this case \(b \in (\delta, 1)\) as shown in the proof of Propositions 1 and 2. Q.E.D.

**Proof of Proposition 5.** Consider the function \(F(B; \alpha)\) introduced in the proof of Propositions 1 and 2. For any \(\alpha \in [0, \bar{\alpha})\), the function \(F(\cdot; \alpha)\) is continuously differentiable over \(\mathbb{R}\). Take any pair \(\alpha', \alpha'' \in [0, \bar{\alpha})\) with \(\alpha'' > \alpha',\) and let \(B'\) and \(B''\) be the unique solutions to \(F(B; \alpha) = B\), respectively for \(\alpha = \alpha'\) and \(\alpha = \alpha''\) (existence and uniqueness of such solutions follows directly from Proposition 2). Furthermore, as shown in the proof of Propositions 1 and 2, \(F(B; \alpha') > B > 0\) for all \(B \in [0, B']\). Simple algebra then shows that \(\partial F(B; \alpha)/\partial \alpha \geq 0\) for any \(B \geq 0\), with strict inequality if \(B > 0\). It follows that \(B'' > B'\). The result in the proposition then follows from the fact that \(b \equiv B/(1+B)\) along with the fact that the contribution of noise to volatility is increasing in \(b\). Q.E.D.

**Proof of Proposition 6.** Aggregate welfare is given by

\[
W(b, \tilde{b}, c) \equiv \mathbb{E} \left[ n(x, y) (\beta Q(\Theta; \hat{\theta}) - 1) \right],
\]
In the proof of Proposition 1 we showed that a contradiction. We have

where

\[ Q(\Theta, \hat{\Theta}) = \beta(\Theta - a\hat{\Theta})(\alpha\beta\hat{\Theta})^{\frac{n}{1 - \sigma}}, \]
\[ \hat{\Theta} = e^{\theta + \frac{1}{2}\pi^{-1}}, \quad \hat{\theta} = \frac{\pi\omega}{\pi} (\theta + \eta) + \frac{\pi}{\pi} z, \quad z = \theta + b\varepsilon, \]  
\[ \pi = \pi_\theta + \pi_\omega + \pi_z, \quad \pi_z = \pi_y/b^2, \]

and with the startup rule given by

\[ n(x, y) = 1 \iff (1 - \tilde{b})x + \tilde{b}y \geq c. \]

For convenience, we are introducing two different coefficients \( b \) and \( \tilde{b} \): \( b \) captures the informativeness of the signal \( z \), \( \tilde{b} \) is the coefficient in the startup rule. Of course, for consistency, the planner must choose \( b = \tilde{b} \). Therefore, the planner’s optimization problem is

\[ \max_{b, c} W(b, b, c). \]

We want to show that it is optimal to choose a \( b < b^* \), where \( b^* \) is the coefficient in the market equilibrium (recall that the latter is unique when \( a \) is small enough). The argument is by contradiction. Suppose it is optimal to choose a pair \((b, c)\) with \( b \geq b^* \). Then we want to show that there is a \((b', c')\), with \( b' < b \), that delivers higher welfare. We do it in two steps. First, we show that there is a pair \((b', c')\), with \( b' < b \), such that \( W(b, b', c') > W(b, b, c) \). That is, fixing the precision of the endogenous public signal, it is optimal to choose a startup rule less sensitive to the signal with correlated noise. Second, we show that a more informative endogenous signal increases welfare, that is, \( W(b', b', c') > W(b, b', c') \). Combining the two inequalities we have

\[ W(b', b', c') > W(b, b, c), \]

a contradiction.

**Step 1.** Define expected social surplus conditional on \( x, y \) as

\[ S(x, y) = \mathbb{E}[\beta Q(\Theta, \hat{\Theta}) - 1|x, y] = \beta^2(\alpha\beta)^{\frac{n}{1 - \sigma}} \mathbb{E}[\Theta\hat{\Theta}^{\frac{n}{1 - \sigma}}] - \beta(\alpha\beta)^{\frac{n}{1 - \sigma}} \mathbb{E}[\hat{\Theta}^{\frac{n}{1 - \sigma}}] - 1. \]

In the proof of Proposition 1 we showed that

\[ \mathbb{E}[\Theta \cdot \hat{\Theta}^{\frac{n}{1 - \sigma}}|x, y] = \exp \left\{ \frac{1}{1 - a} \mathbb{E}[(1 - \alpha)\theta + a\hat{\theta}|x, y] + \frac{a}{2(1 - a)} Var((1 - \alpha)\theta + a\hat{\theta}|x, y) \right\}, \]

where

\[ \frac{1}{1 - a} \mathbb{E}[(1 - \alpha)\theta + a\hat{\theta}|x, y] = q_x x + q_y y, \]

with

\[ q_x = \frac{1}{1 - a} \left( 1 - \alpha + \frac{\pi \omega + \pi z (1 - b)}{\pi} \right) \delta_x, \]
\[ q_y = \frac{1}{1 - a} \left( 1 - \alpha + \frac{\pi \omega + \pi z (1 - b)}{\pi} \right) \delta_y + \frac{1}{1 - a} \left( \frac{\pi z b}{\pi} \right) \]

37
and where $\text{Var} \left( (1 - \alpha) \theta + \alpha \hat{\theta} | x, y \right)$ is invariant in $(x, y)$, as shown in (38).

Following similar steps, we can derive

$$
\mathbb{E} \left[ \hat{\Theta}_{y \mid x} \right] = \exp \left\{ \frac{1}{1 - \alpha} \mathbb{E} [\hat{\theta} | x, y] + \frac{\pi^{-1}}{2(1 - \alpha)} + \frac{1}{2(1 - \alpha)^2} \text{Var}(\hat{\theta} | x, y) \right\},
$$

where

$$
\frac{1}{1 - \alpha} \mathbb{E} [\hat{\theta} | x, y] = \hat{q}_x x + \hat{q}_y y,
$$

with

$$
\hat{q}_x = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_x,
$$

$$
\hat{q}_y = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_y + \frac{1}{1 - \alpha} \frac{\pi z b}{\pi} b
$$

and where $\text{Var}(\hat{\theta} | x, y)$ is invariant in $(x, y)$.

It follows that we can write expected surplus as

$$
S(x, y) = Q_1 e^{q_x x + q_y y} - Q_2 e^{\hat{q}_x x + \hat{q}_y y} - 1,
$$

where $Q_1$ and $Q_2$ are positive constant terms.

It will be useful to derive some properties of the coefficients $q_x, q_y, \hat{q}_x, \hat{q}_y$. The coefficients are all positive and satisfy the inequalities $\hat{q}_x < q_x$ and $\hat{q}_y/\hat{q}_x > q_y/q_x$. The first inequality follows immediately from $(\pi \omega + \pi z (1 - b))/\pi < 1$. The second inequality follows from the fact that the expression

$$
(1 - \bar{\alpha} + \bar{\alpha} \frac{\pi \omega + \pi z (1 - b)}{\pi}) \delta_y + \bar{\alpha} \frac{\pi z b}{\pi} b
$$

$$
(1 - \bar{\alpha} + \bar{\alpha} \frac{\pi \omega + \pi z (1 - b)}{\pi}) \delta_x
$$

is an increasing function of $\bar{\alpha}$, is equal to $q_y/q_x$ when $\bar{\alpha} = \alpha$, and is equal to $\hat{q}_y/\hat{q}_x$ when $\bar{\alpha} = 1$. Finally, we can prove that

$$
\frac{q_y}{q_x} = F \left( \frac{b}{1 - b} \right) < \frac{b}{1 - b'},
$$

where the function $F$ is defined in the proof of Proposition 2. The equality can be proved comparing the expressions for $q_x$ and $q_y$ above with the definition of $F$ in that proof. The inequality follows from the fact that the equilibrium is unique, so the $F$ function can only cross the 45 degree line once, from above, at $b/(1 - b')$, and from the fact that, by hypothesis, we have $b > b^*$.

We can now prove two lemmas.

**Lemma 3.** For each $y$ there is a unique $x$ such that $S(x, y) = 0$, $S(x', y) > 0$ if $x' > x$ and $S(x', y) < 0$ if $x' < x$.

**Proof of Lemma 3.** Existence: Fix any $y \in (-\infty, \infty)$. Notice that $\lim_{x \to -\infty} S(x, y) = -1$. Rewrite

$$
S(x, y) = e^{q_x x + q_y y} \left[ Q_1 - Q_2 e^{(\hat{q}_x - q_x) x + (\hat{q}_y - q_y) y} \right] - 1,
$$

where

$$
q_x = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_x,
$$

$$
q_y = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_y + \frac{1}{1 - \alpha} \frac{\pi z b}{\pi} b.
$$

and

$$
\hat{q}_x = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_x,
$$

$$
\hat{q}_y = \frac{1}{1 - \alpha} \left( \frac{\pi \omega + \pi z (1 - b)}{\pi \omega + \pi z (1 - b)} \right) \delta_y + \frac{1}{1 - \alpha} \frac{\pi z b}{\pi} b.
$$

and notice that $q_x - q_x < 0$, so the term in square brackets converges to $Q_1$ as $x \to \infty$, so $\lim_{x \to \infty} S(x, y) = \infty$. By continuity, there exists an $x$ such that $S(x, y) = 0$. Uniqueness: Differentiating we have

$$S_x(x, y) = q_x Q_1 e^{\hat{q}_x x + \hat{q}_y y} - \hat{q}_x Q_2 e^{\hat{q}_x x + \hat{q}_y y},$$

so at a $(x, y)$ such that $S(x, y) = 0$ we have

$$S_x(x, y) = q_x - \hat{q}_x w > 0,$$

where

$$w \equiv \frac{Q_2 e^{\hat{q}_x x + \hat{q}_y y}}{1 + Q_2 e^{\hat{q}_x x + \hat{q}_y y}} \in (0, 1). \quad (47)$$

An index argument implies a unique solution and a continuity argument implies the inequalities.

**Lemma 4.** The slope of the locus $\{ (x, y) : S(x, y) = 0 \}$ satisfies

$$\frac{dx}{dy} > -\frac{q_y}{q_x},$$

everywhere.

**Proof of Lemma 4.** Differentiating, we have

$$S_y(x, y) = q_y Q_1 e^{\hat{q}_x x + \hat{q}_y y} - \hat{q}_y Q_2 e^{\hat{q}_x x + \hat{q}_y y}.$$

Therefore, the slope is given by

$$\frac{dx}{dy} = -\frac{S_y}{S_x} = -\frac{q_y - \hat{q}_y w}{q_x - \hat{q}_x w} > -\frac{q_y}{q_x},$$

where $w$ is given in (47). The last inequality follows from $w > 0$, $q_x - \hat{q}_x w > 0$ and $\hat{q}_y / \hat{q}_x > q_y / q_x$.

To complete this step we use a graphical argument. In Figure 2 the locus $S(x, y) = 0$ is represented by the solid line. For values to the right of the solid line we have $S(x, y) > 0$, and for values to the left $S(x, y) < 0$. Suppose that the planner is using the conjectured optimal startup rule with $\bar{b} = b > b^*$. Such a rule is represented by the dashed line, which represents the points where $(1 - b)x + by = c$. The dashed line must cross the locus $S(x, y) = 0$ at least at one point or it would be optimal to change $c$ and shift the dashed line. Moreover, it can only cross it at one point, from below, given the result in Lemma 4 and the fact that $q_y / q_x < b/(1 - b)$ as shown above. Consider an alternative startup rule, given by the dotted line, which has $b' < b$ and a $c'$ such that the two rules cross the locus $S(x, y) = 0$ in the same point. This rule delivers a higher expected welfare given that (i) it reduces the size of the region in which $n = 0$ is chosen and $S(x, y) > 0$, (ii) it reduces the size of the region in which $n = 1$ is chosen and $S(x, y) < 0$, and (iii) leaves all other choices of $n$ unchanged. We conclude that

$$W(b, b', c') > W(b, b, c).$$

**Step 2.** We want to prove that

$$W(b', b', c') > W(b, b', c').$$
Let us first establish a result on the benefits of basing investment decisions on a more informative signal. Let

\[ z_1 = \theta + b_1 \varepsilon, \quad z_2 = \theta + b_2 \varepsilon \]

and assume \( b_2 > b_1 \). Similarly, define the random variable \( \hat{\Theta}_j \) and the parameters \( \pi_{z_j} \) and \( \pi_j \) using (45)-(46) with \( b = b_j \), for \( j = 1, 2 \). The unconditional version of the next lemma is just Blackwell's theorem. For our argument, however, we need to prove the conditional version stated below.

**Lemma 5.** For all \((\omega, z_1)\), the following is true:

\[
E[Q(\Theta, \hat{\Theta}_1)|z_1, \omega] > E[Q(\Theta, \hat{\Theta}_2)|z_1, \omega].
\]

**Proof of Lemma 5.** Recall that

\[
Q(\Theta, \hat{\Theta}_j) = \beta \Theta f(K(\hat{\Theta}_j)) - K(\hat{\Theta}_j)
\]

for \( j = 1, 2 \), and notice that the function \( \Theta f(k) - k \) is concave in \( k \). Then we have

\[
E[Q(\Theta, \hat{\Theta}_2)|z_1, \omega] \leq E[Q(\Theta, \hat{\Theta}_1)|z_1, \omega] + E[(\beta \Theta f'(K(\hat{\Theta}_1)) - 1)(K(\hat{\Theta}_2) - K(\hat{\Theta}_1))|z_1, \omega],
\]

and to prove our claim we need to show that the last term on the right-hand side is negative. Recall the optimality condition for \( K(\hat{\Theta}_1) \)

\[
\beta \hat{\Theta}_1 f'(K(\hat{\Theta}_1)) = 1.
\]

Using this condition, the last term on the right-hand side of (48) simplifies to

\[
(a \beta)^{1/a} E[(\Theta/\hat{\Theta}_1 - 1)\hat{\Theta}_2^{1-1/a}|z_1, \omega],
\]
and to prove that this expression is smaller than 0 we need to prove the inequality

$$E[\Theta \Theta_z | z_1, \omega] < E[\Theta_z | z_1, \omega]E[\Theta | z_1, \omega].$$

Because of the normality of the underlying shocks, this condition is equivalent to $Cov[\theta, \hat{\theta}_2 | z_1, \omega] < 0$, which in turn is equivalent to $Cov[\theta, z_2 | z_1, \omega] < 0$, given that $\hat{\theta}_2 = \frac{\pi_2}{\pi_z} \omega + \frac{\pi_{z2}}{\pi_z} z_2$. The following step completes the argument

$$Cov[\theta, z_2 | z_1, \omega] = Cov[\theta, (1 - b_2/b_1)\theta + (b_2/b_1)z_1 | z_1, \omega] = -(b_2/b_1) Var[\theta | z_1, \omega] < 0.$$

Given the startup rule $(b', c')$ we can define

$$N(z') = \Phi\left(\frac{\sqrt{\pi} b'}{\sqrt{2}}(z' - c')\right),$$

where $z' = \theta + b' \epsilon$, and write social welfare under the two information sets for investment as

$$W(b, b', c') = E[N(z')(Q(\Theta, \hat{\Theta} - 1)), W(b', b', c') = E[N(z')(Q(\Theta, \hat{\Theta} - 1)].$$

Since in the previous step we have chosen $b' \prec b$, we can use Lemma 5 to obtain

$$N(z')E[(Q(\Theta, \hat{\Theta}) - 1)|z', \omega] < N(z')E[(Q(\Theta, \hat{\Theta}' - 1)|z', \omega].$$

Taking expectations on both sides completes the proof. Q.E.D.

**Proof of Proposition 7.** Consider the following broader class of subsidies/payments contingent on period-2 information which includes the one in the proposition as a special case. Each entrepreneur $i \in [0, N]$ who started a project receives a subsidy (alternatively, is asked to pay a tax) at the end of period 2 (i.e., after his IPO is completed and the capital investment $k$ is finalized) equal to

$$\sigma(p, N) = \frac{1}{\beta} \left(1 - \exp\{A\Phi^{-1}(N) + B \ln(p) + C\}\right)$$

where $A, B, C \in \mathbb{R}$ and where $p$ denotes the average IPO price. Below we show that, by selecting appropriately, the planner can induce the entrepreneurs to follow the socially-optimal startup of Proposition 6. Because the subsidy/tax is paid at the end of period 2 once $k$ is sunk and does not depend on the outcome $(k_i, s_i, p_i)$ of entrepreneur $i$’s individual IPO, it does not affect the expansion made at $t = 2$ (that is, it has no impact on the supply and demand schedules submitted at the IPO stage). Furthermore, given the investors’ information, the period-2 investments are efficient in the absence of policy interventions, that the proposed policies induce efficiency in the startup decisions also guarantees that they induce efficiency in the subsequent investment decisions.

Under the proposed policy, each entrepreneur starts a project if and only if $E_i[\beta^2(1 - \alpha)\Theta f(K(\hat{\Theta})) + \beta \sigma] \geq 1$ or, equivalently,

$$\beta^2(1 - \alpha)(\alpha \beta)^{\frac{\alpha}{\alpha - 1}} E_i[\Theta \cdot \hat{\Theta}^{\frac{\alpha}{\alpha - 1}}] + \beta E_i[\sigma] \geq 1.$$  

(49)
When all entrepreneurs \( j \neq i \) follow the efficient linear startup rule, that is, start a project if and only if \((1 - b^\circ)x_j + b^\circ y \geq c^\circ\), the information contained in the aggregate startup activity

\[
N = \Phi \left( \frac{\pi}{1 - b^\circ} \right) \left( (1 - b^\circ)\theta + b^\circ y - c^\circ \right)
\]

(50)
is the same as the one contained in the endogenous signal \( z = \theta + b^\circ \varepsilon \) with precision \( \pi_z = \pi_y / (b^\circ)^2 \). Furthermore, because the investors' expected value of \( \theta \), which is given by

\[
\hat{\theta} = \frac{\pi_\omega}{\pi_\omega + \pi_z} \omega + \frac{\pi_z}{\pi_\omega + \pi_z} z_i
\]
is normally distributed, then

\[
\mathbb{E}_i \left[ \Theta \cdot \hat{\Theta}^{\pi_\alpha} \right] = \exp \left\{ \mathbb{E}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] + \frac{\alpha}{1 - \alpha} \frac{1}{2} \pi^{-1} + \frac{1}{2} \text{Var}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] \right\}
\]

where \( \pi = \pi_\omega + \pi_z \) and where \( \text{Var}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] \) is invariant to entrepreneur \( i \)'s information \((x_i, y)\).

Now suppose that \( 1 - \beta \sigma \) is log-normally distributed, meaning that \( 1 - \beta \sigma = \exp \{ g \} \) with \( g \) normally distributed with a variance that is invariant to entrepreneur \( i \)'s information \((x_i, y)\). Then

\[
\mathbb{E}_i \left[ 1 - \beta \sigma \right] = \exp \left\{ \mathbb{E}_i [g] + \frac{1}{2} \text{Var}_i [g] \right\}.
\]

It follows that entrepreneur \( i \)'s startup rule (49) can be rewritten as

\[
\beta^2 (1 - \alpha)(\alpha \beta)^{\pi_\alpha} \exp \left\{ \mathbb{E}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] + \frac{\alpha}{1 - \alpha} \frac{1}{2} \pi^{-1} + \frac{1}{2} \text{Var}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] \right\} \geq \exp \left\{ \mathbb{E}_i [g] + \frac{1}{2} \text{Var}_i [g] \right\},
\]

which is equivalent to

\[
\mathbb{E}_i \left[ (1 - \alpha)\theta + a\hat{\theta} - (1 - \alpha) g \right] \geq M
\]

where

\[
M \equiv \frac{1 - \alpha}{2} \text{Var}_i [g] - \frac{1 - \alpha}{2} \text{Var}_i \left[ \frac{(1 - \alpha)\theta + a\hat{\theta}}{1 - \alpha} \right] - (1 - \alpha) \ln \left\{ \beta^2 (1 - \alpha)(\alpha \beta)^{\pi_\alpha} \right\} - \frac{\alpha}{2} \pi^{-1}.
\]

Now use (50) along with the fact that

\[
p = P(\hat{\Theta}) = \alpha^{\frac{\pi_\alpha}{\pi_\omega}} (\beta \hat{\Theta})^{\frac{1}{\pi_\alpha}}
\]

with

\[
\hat{\Theta} = \exp \left\{ \hat{\theta} + \frac{1}{2} \pi^{-1} \right\}
\]

to observe that, for any \((A, B, C) \in \mathbb{R}^3\),

\[
A\Phi^{-1}(N) + B \ln(p) + C = \sqrt{\pi_x} A \theta + \frac{A b^\circ \sqrt{\pi_x}}{1 - b^\circ} y + \frac{B}{1 - \alpha} \hat{\theta} + \left\{ \frac{B}{1 - \alpha} \left( \ln(\alpha^\circ) \beta^\circ \right) + \frac{\pi^{-1}}{2} \right\} - \frac{A e^\circ \sqrt{\pi_x}}{1 - b^\circ} + C.
\]

This means that when

\[
g = A\Phi^{-1}(N) + B \ln(p) + C
\]

42
then \( g \) is indeed normally distributed with a variance that is invariant to \((x, y)\).

Furthermore, when \( g \) takes the form above

\[
E_i \left[ (1 - \alpha) \theta + a \hat{\theta} - (1 - \alpha) g \right] = E_i \left[ (1 - \alpha) \left( 1 - \sqrt{\pi_x} A \right) \theta + (\alpha - B) \hat{\theta} - (1 - \alpha) \frac{Ab^\delta \sqrt{\pi_x}}{1 - b^\delta} y \right] - D
\]

where

\[
D \equiv (1 - \alpha) \left\{ B \frac{1}{1 - \alpha} \left( \ln \left( a^\alpha b^\beta \right) + \frac{\pi^{-1}}{2} \right) - \frac{Ac^\delta \sqrt{\pi_x}}{1 - b^\delta} + C \right\}.
\]

Next recall that

\[
E_i [\theta] = \delta_x x_i + \delta_y,
\]

and that

\[
E_i [\hat{\theta}] = \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \left( \delta_x x_i + \delta_y y \right) + \frac{\pi_z}{\pi} b^\delta y,
\]

where

\[
\delta_x = \frac{\pi_x}{\pi + \pi_x + \pi_y} \quad \text{and} \quad \delta_y = \frac{\pi_y}{\pi + \pi_x + \pi_y}.
\]

This means that

\[
E_i \left[ (1 - \alpha) \theta + a \hat{\theta} - (1 - \alpha) g \right] = S_x x_i + S_y y - D
\]

where

\[
S_x = \left\{ (1 - \alpha) \left( 1 - \sqrt{\pi_x} A \right) + (\alpha - B) \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \right\} \delta_x
\]

and

\[
S_y = \left\{ (1 - \alpha) \left( 1 - \sqrt{\pi_x} A \right) + (\alpha - B) \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \right\} \delta_y + (\alpha - B) \frac{\pi_z}{\pi} b^\delta - (1 - \alpha) \frac{Ab^\delta \sqrt{\pi_x}}{1 - b^\delta}.
\]

It follows that, under the proposed policy, each entrepreneur starts a project if and only if

\[(1 - b^\delta) x_i + b^\delta y \geq c^\delta\]

where

\[
b^\delta = \frac{\left\{ (1 - \alpha) \left( 1 - \sqrt{\pi_x} A \right) + (\alpha - B) \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \right\} \delta_x + (\alpha - B) \frac{\pi_z}{\pi} b^\delta - (1 - \alpha) \frac{Ab^\delta \sqrt{\pi_x}}{1 - b^\delta}}{(1 - \alpha) \left( 1 - \sqrt{\pi_x} A \right) + (\alpha - B) \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \left( \delta_x + \delta_y \right) + (\alpha - B) \frac{\pi_z}{\pi} b^\delta - (1 - \alpha) \frac{Ab^\delta \sqrt{\pi_x}}{1 - b^\delta}}
\]

and

\[
c^\delta = \frac{M + D}{\left( 1 - \alpha \right) \left( 1 - \sqrt{\pi_x} A \right) + (\alpha - B) \left( \frac{\pi_x + \pi_z (1 - b^\delta)}{\pi} \right) \left( \delta_x + \delta_y \right) + (\alpha - B) \frac{\pi_z}{\pi} b^\delta - (1 - \alpha) \frac{Ab^\delta \sqrt{\pi_x}}{1 - b^\delta}}.
\]

Note that, given \( A \) and \( B \), \( \text{Var} \left[ g \right] \) is invariant to \( C \). This means that, given \( A \) and \( B \), there always exists \( C \) such that \( c^\delta = c^\odot \). It is also easy to see that there exist infinitely many combinations of \( A \) and \( B \) such that \( b^\delta = b^\odot \).

The result in the proposition then follows from specializing the subsidy/tax above to the case where \( A = 0 \). Q.E.D.
Proof of Lemma 2. The investor’s budget constraints are now given by
\[ l = \int_{i \in [0,N]} p_i s_i di \quad \text{and} \quad c_3 = \int_{i \in [0,N]} s_i \Theta f(k_i) di. \]
Let \( \beta = 1 \) to simplify the analysis. We then have that
\[ V = u\left( u^{-1} \left( \mathbb{E}_2 \left[ u\left( \int_{i \in [0,N]} s_i \Theta f(k_i) di \right) \right] \right) \right) - \frac{1}{1 + \epsilon} \left( \int_{i \in [0,N]} p_i s_i di \right)^{1+\epsilon}. \]
Because \( N \) and \( \{s_i, k_i\}_{i \in [0,N]} \) (but not \( \Theta \)) are known to the investor, the above reduces to
\[ V = \frac{1-\sigma}{1-\sigma} \left( \int_{i \in [0,N]} s_i \tilde{\Theta} f(k_i) di \right) - \frac{1}{1 + \epsilon} \left( \int_{i \in [0,N]} p_i s_i di \right)^{1+\epsilon} \]
where
\[ \tilde{\Theta} \equiv u^{-1} (\mathbb{E}_2 [u(\Theta)]) = \hat{\Theta} \cdot \exp \left\{ -\frac{\gamma}{2} \text{Var}(\theta, \mathcal{F}) \right\} \]
is the risk-adjusted expectation of \( \Theta \) and \( \hat{\Theta} \equiv \mathbb{E}_2 [\Theta] \) is as in the baseline model.

The investor’s problem can then be re-expressed in terms of the following Lagrangian:
\[
\mathcal{L} = \frac{1}{1-\sigma} (X)^{1-\sigma} - \lambda^{-1} \left( \int_{i \in [0,N]} s_i \tilde{\Theta} f(k_i) di \right) - \lambda \left( \int_{i \in [0,N]} s_i \tilde{\Theta} f(k_i) di \right) - \chi \left( \int_{i \in [0,N]} p_i s_i di - Z \right)
\]
\[ = \frac{1}{1-\sigma} (X)^{1-\sigma} - \lambda^{-1} (X) + \chi Z - \frac{1}{1+\epsilon} (Z)^{1+\epsilon} + \int_{i \in [0,N]} \left\{ \lambda^{-1} s_i \tilde{\Theta} f(k_i) - \chi p_i s_i \right\} di. \]
The FOCs for the maximization of the above Lagrangian give
\[ \lambda^{-1} = X^{-\sigma} \]
\[ \chi = Z^\epsilon \]
and
\[ \lambda \chi p_i = \tilde{\Theta} f(k_i). \]
Combining the above conditions with the expansion-feasibility condition
\[ k_i = p_i s_i \]
we conclude that each entrepreneur \( i \)'s profit is given by
\[ \Pi_i = (1 - s_i) \Theta f(k_i) = \frac{\Theta}{\tilde{\Theta}} \left\{ \tilde{\Theta} f(k_i) - \lambda \chi k_i \right\} \]
and hence that the value of \( k_i \) that maximizes \( \Pi_i \) now solves
\[ \tilde{\Theta} f'(k_i) = \lambda \chi. \]
This also makes clear that \( \lambda \chi \) is the marginal cost of investment faced by the typical entrepreneur.

With Cobb-Douglas, the above gives \( a \tilde{\Theta} k_i^{\alpha-1} = \lambda \chi \) which, together with \( \tilde{\Theta} f(k_i) = \lambda \chi p_i \) and \( k_i = s_i p_i \) verifies that
\[ s_i = \alpha \]
44
for all $i$, and hence that $k_i = k$ for all $i$, as in the baseline model. It follows that

$$X = \int_{i \in [0, N]} s_i \tilde{\Theta} f(k_i) di = \alpha N \tilde{\Theta} k^a$$

$$Z = \int_{i \in [0, N]} p_i s_i di = \int_{i \in [0, N]} k_i di = Nk$$

and hence that

$$\lambda \chi = X^\alpha Z^\epsilon = (\alpha N \tilde{\Theta} k^a)^\alpha (Nk)^\epsilon.$$

The equilibrium condition for $k$ then becomes

$$\alpha \tilde{\Theta} k^{a-1} = \lambda \chi = (\alpha N \tilde{\Theta} k^a)^\alpha (Nk)^\epsilon.$$

Q.E.D.

**Proof of Proposition 8.** Using (29) from Lemma 2, we have that the equilibrium level of investment is given by

$$k = K(\tilde{\Theta}, N) \equiv (\alpha^{1-\sigma} \tilde{\Theta}^{1-\sigma} N^{-\sigma-\epsilon})^{1/(1-\sigma+\epsilon)}.$$

Replacing the above value of $k$ and $s = \alpha$ into the entrepreneur’s profit function

$$\Pi = (1 - s) \Theta f(k),$$

we have that the payoff from starting a project is given by

$$\Pi = \Pi(\Theta, \tilde{\Theta}, N) \equiv (1 - \alpha) \Theta (\alpha \tilde{\Theta})^{\frac{1-\sigma}{1-\sigma+\epsilon}} N^{-\frac{\sigma+\epsilon}{1-\sigma+\epsilon}}.$$

The entrepreneur’s optimality condition for starting a project, $E_i [\Pi] \geq 1$, then reduces to

$$E_i \left[ \Theta \tilde{\Theta}^{\frac{a(1-\sigma)}{1-a(1-\sigma)+\epsilon}} N^{-\frac{\sigma+\epsilon}{1-a(1-\sigma)+\epsilon}} \right] \geq \tilde{c},$$

where $\tilde{c} \equiv \left( (1 - \alpha)(\alpha)^{\frac{a(1-\sigma)}{1-a(1-\sigma)+\epsilon}} \right)^{-1}$. Letting $\bar{\theta} \equiv \log \tilde{\Theta}$, $\varphi \equiv \alpha(1 - \sigma)/(1 + \epsilon)$ and $\psi \equiv \varphi \equiv \alpha(\sigma + \epsilon)/(1 + \epsilon)$, we have that the latter condition is equivalent to

$$E_i \left[ \exp \left\{ \frac{1+\epsilon}{1-a(1-\sigma)+\epsilon} \left[ (1 - \varphi) \theta + \varphi \theta - \psi \log N \right] \right\} \right] \geq \tilde{c},$$

as claimed. Q.E.D.
